January-December 1955

including

PUBLIC HEALTH MONOGRAPHS

1955 Titles, Numbers 25-35

U. S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE
MARION B. FOLSOM, *Secretary*
PUBLIC HEALTH SERVICE
LEONARD A. SCHEELÉ, *Surgeon General*

THIS INDEX to *Public Health Reports* is divided into two parts: a subject and an author index.

In addition to the subject headings, categorical headings include: ADMINISTRATION, ANNOUNCEMENTS, APPOINTMENTS, CONFERENCE REPORTS, DEATHS, EVALUATION, EXHIBITS, FILMS, FRONTISPIECES, GRANTS AND FELLOWSHIPS, IDEAS, LEGAL NOTES ON PUBLIC HEALTH, PUBLIC HEALTH MONOGRAPHS, PUBLICATIONS, RECRUITMENT, REVIEWS, TRAINING COURSES AND PROGRAMS.

Titles of articles appear as entries under the appropriate subject heading, followed by the author's name in brackets. One asterisk before the page number indicates an original article; two asterisks indicate a Public Health Monograph, published concurrently with *Public Health Reports*.

Illustrative material on the inside of the front cover of each issue is indexed by month under the heading "FRONTISPIECES." It is recommended, therefore, that the covers be included in a bound volume.

A compiled annual list of Public Health Service publications may be obtained from the Public Inquiries Branch.

Threshold Limits

Notable progress in the establishment of reliable threshold limits, or maximum allowable concentrations, for injurious agents in the workroom air has been made largely during the past decade.

The chaotic situation that existed prior to that time is reflected in the early reports of the American Conference of Governmental Industrial Hygienists. Organized in 1937, this group was one of the first to concern itself with the development of workable, uniform toxicity guides for the provision of a healthful working environment.

In 1942, the Subcommittee on Threshold Limits of the Committee on Technical Standards presented as its first report to the conference a table of the maximum allowable concentrations established by various States for atmospheric contaminants. Values for more than 60 substances were given. Some of these substances were listed as many as three times, reflecting the different values set by the States. The concentration for nitrogen oxides, for example, was 29-70 p.p.m. in 1 State, 40 p.p.m. in 4 States, and 10 p.p.m. in 7 States.

Such variations were based in large part on very limited experience. Gradually, the accumulation of toxicological data and information based on clinical studies of exposed workers, environmental investigations, and animal experimentation has provided a firmer, broader base for the establishment of maximum allowable concentrations.

The 1954 threshold limits list of the American Conference of Governmental Industrial Hygienists presents single values for over 160 different substances. In addition, there is an accompanying tentative list of values under trial and test. Henceforth the tentative list will include all substances not previously listed.

For a review of threshold limits and other limits and tests for safeguarding the health and comfort of the industrial worker, see the paper by Dr. Herbert E. Stokinger on page 1 of this issue.

Aerial view of St. Elizabeths grounds.

St. Elizabeths Marks 100th Anniversary

St. Elizabeths Hospital in Washington, D. C., a part of the Department of Health, Education, and Welfare, marks its centennial this year.

Founded by the Congress in 1855, St. Elizabeths has grown from a set of plans which originally called for 90 beds to a community of more than 7,200 patients. Today, recognized internationally, its signal achievements include pioneer work in neuropathology, special treatment wards and special wards for legal offenders, introduction of hydrotherapy and of the use of Kraepelin's classification of mental disorders for diagnosis.

Some of the earliest American writing on forensic psychiatry started at St. Elizabeths, beginning with the work of Glueck and continuing through that of Karpman. Kempf's volume on psychopathology was written at the hospital. Several of Korzybski's early studies in semantics were made there. Its present superintendent, Dr. Winfred Overholser, is the author of "The Psychiatrist and the Law," published in 1953.

This spring, a new 400-bed treatment and admissions building, to be known as the Dorothea Lynde Dix Pavilion, will be dedicated. Miss Dix, chief nurse for the Union Army during the Civil War, was a dynamic reformer. Her efforts led to the establishment of St. Elizabeths, along with at least 30 State mental hospitals.

This 8-story building will give the Graduate School of Public Health, University of Pittsburgh, its first permanent home since its founding in 1948. The school was established by the A. W. Mellon Educational and Charitable Trust. Dr. Thomas Parran, former Surgeon General of the Public Health Service, is dean.

Preliminary plans for the structure were approved in October 1954. They include two unique features, an "anechoic" chamber and a cobalt room.

In the soundproofed anechoic chamber physicists will be able to conduct measurements of sound, hearing, and noise without troublesome interference from reflections or echoes which would otherwise invalidate measurements.

The cobalt room will provide a protected area for storage of radioactive cobalt. The

material is necessary for use in instruments which determine leakage from medicine cobalt bombs now in use in the Pittsburgh district.

The new building will be located directly below Pitt Stadium and across from Children's Hospital. It will have an auditorium capable of seating 282.

The first two floors will house administrative offices, libraries, locker rooms, lounges, and cafeteria facilities. Remaining floors will include classrooms, laboratories, and offices for the departments of biochemistry and nutrition, biostatistics, epidemiology and microbiology, occupational health, and public health practice.

The university is also constructing a new building for its School of Health Professions (medicine, dentistry, nursing, and pharmacy).

An experience related by a Food and Agriculture Organization mission points up the World Health Day theme for 1955,

"Clean Water Means Better Health." An FAO mission was advising the Pakistan Government on a project to control and use the water of the Ganges for agriculture. One day the head of the mission bought some fish from a fisherman in the river's delta—a man who lives on and from the water.

"For payment," said the fisherman, "just give us some fresh water to drink. That and a little rice are what we need."

Dr. M. G. Candau, Director-General of the World Health Organization, stated in his message:

"Abundant supplies of clean water have always been a necessary condition for the rise of the great civilizations of history, such as those nurtured in the valleys of the Nile, the Euphrates, the Indus, the Ganges, and the Yangtze. But as these civilizations flourished, their growing population only too often poisoned the water on which their life depended.

"Although spectacular results have been achieved within the last few decades in Western Europe and North America through the improvement of water supplies and the sanitary disposal of human wastes, no country in the world can yet afford to relax its vigilance.

"We must not forget that serious and widespread cholera and typhoid epidemics were still occurring in Europe and America at the end of the 19th century. As late as 1937, a momentary breakdown in the water purification system of Croydon, near Lon-

don, resulted in a terrible epidemic of typhoid fever.

"In the immediate years following World War II, 250,000 cases of typhoid fever with 25,000 deaths were occurring annually in Europe. In Mexico in 1948, an estimated 22 percent of all deaths were caused by waterborne diseases.

"Experts believe that in many Asian countries the sickness rate could be halved by protecting water supplies and providing proper facilities for the disposal of wastes.

"There is an added need for vigilance in areas where farming methods are being modernized, industries are expanding, and populations are becoming denser. Particularly careful planning is then needed to assure sufficient water supplies for homes, factories, irrigation, and electric power, and to solve the complementary problems of the disposal of sewage and industrial wastes."

frontispiece . . .

Men of Loma de Ramas, a village of 400 inhabitants in El Salvador, transporting pipe for a water supply line. The river crossing was one leg of their trip from the supply depot at Guazapa to the village, over 5 miles of tortuous rock-strewn road and half-way up a mountain. To get fresh, drinkable water for the village, one phase of the WHO and El Salvador general health program, the men, women, and children of the village volunteered to carry the pipes and other equipment. The Papyrus Ebers

The Papyrus Ebers, dating from the first half of the 16th century B. C., is one of the earliest medical works in existence. Primarily a collection of recipes for treating various diseases and symptoms, it constitutes an important source of information about ancient Egyptian medicine. Many of the recipes are attributed to the period 2500–3000 B. C.

The document begins with invocations of the gods and recitals to be spoken when treating a patient, but it also contains between 700 and 800 prescriptions arranged according to organs and diseases, two short treatises on the heart and vessels, and a brief surgical section. Diseases are rarely described.

The prescriptions, which make up the major portion of the papyrus, include both internal and external remedies. Names and amounts of ingredients to be used are specified, and instructions for preparation are given. Drugs were boiled and strained or pounded in a stone mortar. When given as potions, they were mixed with beer, wine, milk, or water. Sometimes the drugs were formed into candy with honey or baked into cakes. Pills were made with bread dough. For ointments, active ingredients were mixed with fat.

Hundreds of substances are mentioned in the prescriptions. Metallic salts—lead, iron, and possibly antimony, for example—were recommended for treating diseases of the eyes; castor oil, colcynth, and senna were used as purgatives; ox liver was prescribed for night blindness; turpentine was one of many remedies for worms.

The treatises on the heart and vessels indicate that the ancient Egyptian physician may have known that the heart is the center of the

vascular system: “The beginning of the physician’s secret: knowledge of the heart’s movement and knowledge of the heart. There are vessels from it to every limb. As to this, when any physician, any surgeon, or any exorcist applies the hands or his fingers to the head, to the back of the head, to the hands, to the place of the stomach, to the arms or to the feet, then he examines the heart, because all his limbs possess its vessels, that is: the heart speaks out of the vessels of every limb.” (Translation by B. Ebbell, 1937.)

Some authorities consider the Papyrus Edwin Smith, a surgical treatise written during the 17th century B. C., the only really scientific work among the several Egyptian papyri, but others regard the Papyrus Ebers as equally valuable for its information in many different fields of medicine. These papyri are a part of the accumulation of medical literature which eventually gave rise to the profession of medical librarianship, as explained in the article. *Medical Librarianship*, by Dr. Estelle Brodman, p. 473 of this issue.

The Papyrus Ebers was purchased by Professor Georg Ebers in 1873, and a facsimile edition, with introduction and vocabulary, was published in 1875. It was first translated in 1890 by H. Joachim, a German physician.

Milwaukee Filtration Plant

The water purification plant, owned and operated by the City of Milwaukee, is located on the west shore of Lake Michigan at the north end of Lake Park and directly east of Linwood Avenue. The site is on land reclaimed from Lake Michigan and occupies approximately 26 acres.

The purification plant is of the mechanical or rapid sand type. It has a capacity of 200 million gallons per 24 hours at a filtering rate of 2 gallons per square foot per minute. There are 32 filters, each having a capacity of 6.25 million gallons per day. When operated at the 200 m.g.d rate, there is 1 hour for mixing and 4 hours for settling.

Shown on the frontispiece are the exterior of the filter plant, a view of the ton containers of chlorine, and two of the chlorine feeding machines.

MARION B. FOLSOM, *Secretary*

PUBLIC HEALTH SERVICE

LEONARD A. SCHEELE, *Surgeon General*

A review of what toxicologists and industrial hygienists are doing to develop threshold limits for concentrations of substances in the air, corresponding biological threshold limits, pretoxicosis tests, and prophylactic and antidotal agents . . . and a discussion of recent developments in the techniques of air sampling and air analysis.

Standards for Safeguarding the Health Of the Industrial Worker

By HERBERT E. STOKINGER, Ph.D.

THE EPITOMICAL STATEMENT made some years ago by Dr. James A. Sterner, now medical director of Eastman Kodak Co. and past president of the American Industrial Hygiene Association, announced a change of attitude among industrial hygienists which today is the keynote of enlightened occupational health practice: "No substance is so toxic that it cannot be used if sufficient knowledge of its action has been made available; similarly, no substance is so nontoxic that it should be used without regard to caution."

Currently, several effective means by which such a concept may be implemented are available: (a) threshold limits for concentrations of

injurious agents in the workroom air, (b) threshold limits of concentrations of injurious agents or their metabolic products in biological fluids corresponding to the threshold limits for air (biological threshold limits), (c) tests of pretoxicosis to screen persons for early signs of injury from exposure to hazardous agents, and (d) prophylactic and antidotal agents.

Occupational hygiene standards in this country have been given various names, the most familiar of which is maximal allowable concentrations. Another designation is threshold limit values, the name used by the American Conference of Governmental Industrial Hygienists. Still another term is industrial hygiene standards, a designation recently adopted by the American Standards Association. All these terms refer essentially to the same concept of permissible contamination of workroom air by dusts, fumes, mists, vapors, or gases, although the bases on which the limits for certain substances are set may differ somewhat in the different lists. The following discussion will be confined chiefly to the list of threshold limit values, with which the author is most familiar. This list is prepared by the American Conference of Governmental Industrial Hygienists' Committee on Threshold Limits, which is composed of persons work-

Dr. Stokinger is chief toxicologist, Occupational Health Program of the Public Health Service, Cincinnati, Ohio. He is a member of the Subcommittee on Toxicology, National Research Council; the Committee on Threshold Limits, American Conference of Governmental Industrial Hygienists; and the board of directors, American Industrial Hygiene Association; and a liaison member of the American Standards Association. Formerly, Dr. Stokinger was chief of the Industrial Hygiene Section, Atomic Energy Project, Rochester, N. Y.

g in State and local industrial hygiene departments and in Federal industrial hygiene units, and members of the armed services in the United States and Canada.

Only the United States and Russia appear to be currently developing such lists as the threshold limits list, other countries preferring to use those already developed. Partly because of this, but more especially because the abbreviated preface to the list only briefly refers to its application, the following paragraphs discuss in some detail the nature of the list and its purpose, methods by which the values are developed, and interpretation and proper usage of the values.

Nature and Purpose of the List

The threshold limits list includes those natural minerals and oils and chemical substances, including economic poisons but excluding radioactive materials, in the form of dust, fume, mist, vapor or gas, which are in sufficiently wide use industrially to warrant control of their concentration in the breathing zone of the industrial worker. (Permissible levels of exposure to radioactive materials are independently set by various radiation protection committees throughout the world. Values for many radioactive substances may be found in the National Bureau of Standards Handbook No. 52.) Because of the rapid development and application of certain chemical substances, often a time lag occurs between the industrial use of a substance and the appearance of the threshold limit value. This interval, however, is becoming shorter as a result of increasing attention of the chemical industries to the development of data on the toxicity and hazards of their products prior to use. Limiting values assigned to each substance in the list represent the maximal atmospheric concentration to which workers may be exposed repeatedly day after day without injury to health.

The purpose of the list is to provide a limiting value of air concentration for injurious substances for use by plant engineers, industrial hygienists, and others concerned with the health and comfort of the workers. The list is intended to be a guide for the control of working atmospheres and to provide management,

labor unions, and the worker alike an assurance of healthful conditions on the job.

Development of Threshold Limits

A value for a toxic substance is assigned on the basis of data accumulated from animal inhalation toxicity studies and on the basis of industrial experience. Together, these represent, of course, ideal requirements not always fulfilled for each substance in the list but approximated as far as possible. Of the two, industrial experience is the test on which the validity of a value must ultimately rest. Because reliable information from industrial experience is frequently difficult to obtain, the Committee on Threshold Limits is often forced to rely on opinion of industrial hygienists, rather than on factual information, or sometimes, merely on animal data. Such opinions, however, are based on specific experience with various substances and come from occupational hygienists throughout the country. The current toxicological literature is also scanned continually for usable information. When the need for the assignment of a value seems urgent, a tentative value is assigned on the basis of the best information available at the time.

Originally, preventing impairment of health was virtually the only consideration in the selection of the proper limiting air concentration of an injurious substance. Now, however, with the increasing emphasis in occupational health on the "total man," more subtle effects on health, such as the effects of annoying or irritating agents, are also considered. Thus, whereas a threshold limit value of 3 or 4 p.p.m. for chlorine would insure no impairment of workers' health, this value is reduced to 1 p.p.m. in the interest of greater freedom from irritant effects. The levels of other gases and vapors with irritant or other discomforting effects on the workers have been similarly adjusted.

The rapid growth in the number and diversity of industrial substances to which workers are exposed and the increasing attention being given to occupational health in this country have given rise to a very real problem of maintaining the threshold limits list current. To meet this problem, the Committee on Threshold Limits reviews the lists annually, considering

carefully each value and any new information pertaining to a change in level. When a value is changed, it is so designated.

In the threshold limits list for 1954, a further accommodation has been made in an attempt to keep pace with the ever-increasing use of new industrial chemicals. This is the addition of a tentative list separated from the list of established values. Henceforth the tentative list will include all substances not previously listed. Because of the lesser certainty sometimes associated with these tentative values, they should provide only general guidance in the control of exposure and should carry no legal weight. The tentative list is looked upon as providing levels under trial and test, to be revised when new information justifies. Substances in the tentative list will not be incorporated in the main list until the values have been proved by experience to be acceptable. It is hoped that the tentative list will stimulate a greater number of yearly additions than in the past, as well as the critical evaluation of these values by greater numbers of industrial hygienists.

Overall Maximal Upper Limits

It is now considered desirable by a majority of the persons concerned with occupational health to assign a maximal upper limit of 1,000 p.p.m. for most, although not all, of the gases and vapors that are apparently nontoxic or nonhazardous. Such a limit has been set for certain Freons and other apparently innocuous substances, although it is known that neither health nor safety are endangered by exposure to far higher levels under ordinary conditions. In favor of this practice is the argument that it will prevent excessive or wanton exposure to air contaminants. It is recognized that all the facts needed to assure safety are seldom at hand. Physiologically inert substances, such as certain Freons and sulfur hexafluoride, in unlimited concentration may suddenly become hazardous, in the presence of welding or plumbing operations, through decomposition by heat to highly toxic products.

A similar concept is developing with respect to dusts that in the past have been considered

essentially nonhazardous or not incapacitating. Numerous reports from various countries make it all too apparent that many dusts formerly considered inert are capable of producing pulmonary changes that are oftentimes disabling (1-7). It would therefore seem that all insoluble dusts of whatever nature should be held suspect until proved otherwise (4). Unfortunately, the assignment of a specific level for each mineral dust is impossible at present. Mineral dusts are commonly of complex and inconstant composition, often varying according to locality, and thus are potentially capable of causing a variety of physiological responses. As a case in point, pulmonary carcinoma is commonly associated with the long-term inhalation of asbestos in England, but not in America (8). Assignment of specific levels is also difficult because pulmonary changes derived from the inhalation of mineral dusts commonly require years to assess, because sound information relating exposure to response is not, for the most part, available, because exposures are not uniform owing to changes in the industrial process and job changes, and because dusts from operations involving the same materials often differ in size and surface area.

Therefore, it is believed that the validity of the present standards for dust should be reviewed and consideration given to the following suggestions. In the absence of information and in view of the poor prospect of obtaining any in the near future, the conclusion seems inescapable that if protection from dusts is to be guided by hygienic standards, an overall limit value should be selected. Actually, two values appear desirable, one for dusts containing free silica, and another for nonsiliceous dusts.

For silica-bearing dusts, a limit of from 2 to 5 million particles per cubic foot (m.p.p.c.f.) is suggested. It would be applicable to those substances containing free silica of any appreciable percentage (10 percent or more). Such a level appears justifiable on the basis of usage and experience, as shown in table 1, and tacitly assumes no other mineral is more hazardous than silica and/or any combination of a mineral with silica. Actually, this value represents a rather low level of exposure when

expressed in terms of milligrams of substance per cubic meter of air. Depending upon particle size, 5 m.p.p.c.f. silicon dioxide (SiO_2) with a density of 2.2 might range from 0.01 or 0.02 milligram to several milligrams per cubic foot, assuming the general size distribution of industrial dusts thus far recorded by optical methods (9); with dusts differing in density from SiO_2 , corresponding differences in weight concentration, of course, would occur.

The question then arises of how best to express the dustiness of an atmosphere. Although this concerns matters too involved to be entered into here, it would seem that, with an absolute method now available for the measurement of industrial dusts, the limiting concentrations should be expressed in terms of either millions of particles per cubic foot or milligrams per cubic meter, or both, but within a definite size range, this range to be 0-3 μ diameter. Otherwise, dust counts, as well as expressions based on weight per volume of air, become meaningless. Particles of the size 3 μ and below can now be sampled and measured and are believed to be the only ones of hygienic significance. Whether the value approximating 5 m.p.p.c.f. will be found to hold when the submicroscopic particles are included is a very important project for future investigation.

Table 1. Recommended permissible limits of some silica-bearing dusts¹

Industry or source	Reported percent free SiO_2 ²	Recommended concentration m. p. p. c. f.
Sydney sandstone-----	90	³ 6
Silica brick-----	80	2
Gold mining (Union of South Africa)-----	80	⁴ 3
Granite-----	35	9-20
Pottery-----	30	4
Gold mining (Ontario, Canada)-----	25-35	⁴ 8.5
Pyrophyllite-----	30-40	10
Anthracite (hard rock)-----	30	5-10
Nonferrous mines-----	20-40	5-10
Anthracite (haulageways)-----	13	10-15
Cement-----	6	20

¹ From a table prepared by Theodore F. Hatch, professor of industrial hygiene, University of Pittsburgh.

² Values are approximate.

³ Owens Counter.

⁴ Konimeter.

A practical threshold limit value for non-siliceous dusts would appear to be 5 mg./m.³ This value has been in satisfactory use for some years for controlling hematite dust and fume in at least one American plant (10). It would seem to represent a reasonable level of dustiness for all other presently considered "inert" nonsiliceous inorganic dusts.

More Specific Designations

With increasing industrial hygiene knowledge and experience, refinements in designating specific substances to which values are assigned will assuredly follow. As yet, however, only a beginning has been made in this respect. For chromium, the designation specifically refers to chromic acid or to chromates. The highly poisonous arsine gas has a threshold limit value of 0.05 p.p.m., whereas the value for arsenic and its compounds is 0.5 mg./m.³ Differences in toxic action of uranium compounds have been recognized by individualizing the soluble and insoluble compounds.

It would appear that manganese dioxide would be a desirable designation for manganese, because manganese dioxide is the most common industrial hazard of this element. Mercury at 0.1 mg./m.³ should refer to mercury vapor and its inorganic compounds and should not imply inclusion of the more toxic organic mercurials. Similarly, for fluorides the newer organic fluorides which vary widely in toxicity and hazard should be explicitly excluded, and for selenium, the threshold limit should apply only to selenium compounds which are highly toxic, not to elemental selenium dust, which is essentially nontoxic. The value of 0.1 mg./m.³ for cadmium should refer specifically to the cadmium fume, for use of this limit for most of the insoluble cadmium compounds imposes far too severe a restriction. Different levels for lead and its compounds should be specifically defined according to information accumulated in the lead industries in this country over the past 10 years. Data show that whereas there is no reason to alter the value of 0.15 mg./m.³ for lead fume or for lead dust of submicroscopic size, this value is unrealistically severe when applied to the more insoluble lead salts, and probably too lenient if applied to certain or-

ganic lead compounds. These and other desirable refinements in the list will undoubtedly be made in the near future.

Biological Threshold Limits

One new feature of occupational health standards that appears destined to play a useful role in evaluating personnel exposure in industry is what might be called biological threshold values, for want of a better term. These values refer at the present time to the greatest permissible content of an air contaminant or its metabolic derivatives in the body fluids, usually in blood or urine, although changes in other bodily constituents may in time serve also as measures of exposure. A list of biological threshold values, which correspond to the threshold limits for concentrations of the substances in air, is given in table 2. The values given for some of the substances are tentative, having been derived from limited experience; for others, such as lead and fluorine, the values are well founded. For still others, such as arsenic and mercury, there is considerable disagreement among industrial hygienists as to the usefulness of urinary determinations.

It is probable that the biological threshold limits of only a few selected substances will ultimately find an accepted place in occupational hygiene standards, since all substances are not amenable to accurate analysis in body fluids (complex organic molecules) by reason of wide individual variation in metabolism, interferences from dietary sources (arsenic); or simply the relative absence of constituents in easily obtainable body fluids (chromium, manganese, silver, and probably beryllium). For biological values to be serviceable, repeated determinations must be made on each person exposed, and preexposure control determinations are desirable. When biological threshold limits are used, they should supplement determinations of air concentrations, not replace them. In effect, these biological limits substitute diagnosis for the control or prevention of injury provided by air analysis.

Currently, in the lead industry, considerable enthusiasm is being expressed over the ap-

Table 2. Biological threshold limits¹

Substance	Blood (mg./100 ml.)	Urine (mg./l.)
Inorganic constituents		
Arsenic		1 ² (0.5 for arsine or lewisite).
Beryllium		0.002.
Cadmium		0.1.
Copper	0.1	
Chromium		Any detectable amount.
Lead	0.08	0.2.
Mercury		0.25. ³
Manganese ⁴		0.001.
Thorium		Not eliminated in chemically measurable amounts.
Vanadium		0.05. ⁵
Uranium		0.01. ⁵
Fluoride		4.
Selenium		0.07.
Tellurium		0.01.
Organic constituents		
Benzene		15 percent below normal sulfate ratio of inorganic to total sulfate
Bromide	100	
Carbon disulfide		0.15.
Dinitro- <i>o</i> -cresol		5.
Methyl alcohol		5-7.
Methyl acetate		Analyzed as methyl alcohol.
Toluene (as hippuric acid).		3,000.
Trichloroethylene (as trichloroacetic acid).		75.

¹ Many of the values given here are found in or have been revised from Chemistry of Industrial Toxicology by H. B. Elkins, New York City, Wiley, 1950, and in Analyses of Biological Materials as Indices of Exposure to Organic Solvents by Elkins, A. M. A. Arch. Indust. Hyg. and Occup. M. 9. 212-222, March 1954.

² H. H. Schrenk, in New Information on Arsenic Trioxide, Ind. Eng. Chem. 45: 11A (1953), states that urinary arsenic values of 4-5 mg./l. are commonly not associated with signs of arsenic poisoning. Use of urinary values is considered of doubtful worth because of great variation in normal values. Dietary arsenic, such as that obtained from seafoods, would greatly alter the urinary arsenic picture; moreover, arsenic is excreted chiefly in the feces.

³ Urinary values may not always be reliable in long-term exposures owing to possibility of development of lower nephron nephrosis and for other reasons.

⁴ Inasmuch as manganese is eliminated chiefly via the intestine, urinary determination is not a particularly valuable indicator of exposure.

⁵ Tentative value.

parently successful use of urinary lead values with or without prior screening by urinary coproporphyrin determinations. The argument in favor of the use of urinary values is that in practice most industrial exposures are neither uniform nor simple, but are mixed, and, therefore, that the body serves as a better sampling device and indicator of this type of exposure than do air samples. Biological determinations also offer a guide in the diagnosis of illness not provided by air analysis. Whether it is a wise decision to allow the individual to serve as his own indicator of exposure is debatable: Derangement of metabolic function or excretion for various causes is not uncommon among working populations, especially in older age groups, and concomitant exposure to other substances or other stresses may deflect normal metabolic pathways. It would appear reasonable, for the present at least, that biological values should be accompanied by one other independent method of evaluating the working environment.

Interpretation and Use

After the threshold limits have been accepted, it is most important that they be properly interpreted and used. Because there is some lack of agreement among industrial hygienists as to the use of the values, it might be worthwhile to consider what is meant by threshold limit or maximal allowable concentration. Confusion appears to center on the precise meaning of the term "threshold" or what constitutes "maximal allowable." These are brief terms used to express a rather complex and abstract concept which may be explained philosophically and operationally.

Philosophically, the threshold limit represents a level to which a normal healthy worker may be exposed for 8 hours each workday without harm to his physical or mental well-being. Because, in practice, most situations involve intermittent or varying exposures, the concept of the limit is that the summation of physiological effects of such exposures shall not be greater than the effect of exposure to a constant concentration at the level of the limit.

Operationally, the word limit refers to the highest permitted averaged values of an agent

in the workroom air that have been obtained in a complete cycle of operations during the day. Proper averaging of concentrations should take into consideration the duration of exposure at each concentration; this is referred to as a "weighted average." Concentrations far above the limit for periods of 30 minutes or more and prevailing sporadically throughout the day, although possibly equaling the threshold limit, are not within the intended meaning of the term. Such levels come under the classification of acute, high exposures, and suitable measures should be taken to bring such levels in line with the accepted limit. Threshold limit values are not based on high, acute levels superimposed on a persistent lower level irrespective of what value their average is.

Threshold limit values should be used as guides in the control of health hazards and should not be regarded as fine lines between safe and dangerous concentrations, that is, a point above which injury is bound to occur and below which complete safety may be expected for all exposed persons. Competent judgment is required here as in the interpretation of any standard.

Misuse of Limits

The threshold limit values should be used only for control of exposure atmospheres for repeated 8-hour working days. They should not be used in the following ways:

1. For brief acute exposures. (The threshold limit values have been set on the basis of chronic exposures, not on the basis of brief acute exposures.)
2. For mixtures of substances. (There is no assurance that mixtures may not have potentiated and enhanced effects greater than the summated effects of each component.)
3. As levels for community air pollution or for levels to be derived therefrom by simple extrapolation. (The threshold limits have been set on the basis of an 8-hour exposure day with the assumption that a subsequent 16-hour period of nonexposure will aid distribution and elimination of the toxic agent from the body; therefore, they cannot apply to 24-hour continuous exposures common in air pollution conditions.)

4. As levels of permissible concentrations in community water supplies or for substances in solution. (Appropriate levels have been fixed specifically for several toxic elements in potable waters.)

5. As the basis for selecting dangerous compounds for labeling. (Hazards involved in handling chemicals frequently arise from routes other than inhalation, which is the basis for threshold limits.)

6. As safe limits for flight personnel in aviation. (Higher standards of safety and performance are required, and degree and duration of exposure at flight altitude differ from the degree and duration at sea level.)

Pretoxicosis Tests

Closely related to the biological threshold values are tests of pretoxicosis, the detection of subtle metabolic changes in the body before injury of serious proportions has developed. The idea is not new, the first reported test of this sort having been applied to the hematologic reactions of prescurfism by Heim de Balsac in 1908 (11). Although the determination of pre-toxic reaction is unquestionably one of the highly desirable goals of the industrial toxicologist, few such tests have been developed mainly because the mechanism of action of most toxic agents on which such tests are based is not generally known.

A pretoxicosis test for carbon disulfide has been reported by Bourguignon (12). This test is based on the change in chronaxie, which, in turn, depends upon the knowledge of the vascular and neurologic changes caused by carbon disulfide during the early stages of injury. Chronaxie, by definition, is the minimal time that an electric current of standard strength is required for the excitation of the tissue. Bourguignon's report indicates that after men had been exposed to carbon disulfide for only 2 months and before any clinical signs of disease were manifest, their chronaxie changed. Accordingly, this test permitted early detection of intoxication by carbon disulfide.

Another test of pretoxicosis that is promising although it is still in the developmental stage is the lowered cystine content of fingernails of individuals exposed to vanadium. The

lowered content occurs in the absence of any objective or subjective signs or symptoms in the workers, and it has been experimentally demonstrated in the hair of animals ingesting vanadium compounds in amounts that caused no demonstrable signs of toxicity (13). When used in combination with urinary vanadium determinations, the test appears to be highly suggestive of early metabolic changes resulting from exposure to vanadium.

The well-known urinary coproporphyrin III screening test for lead poisoning might well be classed as a pretoxicosis test. Used in combination with urinary lead values, it is now considered a reliable guide to incipient damage by lead (14). At potentially harmful body levels, lead is believed (15) to convert more of the normally occurring colorless precursor to the chromogen while increasing the total coproporphyrin of the urine.

The relative paucity of such procedures attests to the extreme difficulty of their development. Investigators should be encouraged to develop this aspect of preventive medicine, however, because its value obviously transcends that of diagnostic tests of established disease.

Prophylactic and Antidotal Agents

As the realization of the importance of toxicology in the development and safe use of industrial chemicals has widened, more diversified groups of scientists have become attracted to its problems. Such attraction has resulted in the development of a metal complexing agent, the calcium salt of ethylene diamine tetraacetic acid (CaEDTA), for the treatment of lead poisoning (16). This chelating agent has been given good evidence of effectiveness in numerous clinical trials (17, 18), and it gives promise of considerable versatility. It has been found, for example, to be a satisfactory antidote in experimental vanadium poisoning (19) and to give promise in the treatment of essential hypertension (20). Further use of CaEDTA for the more rapid elimination of other toxic metals having the capacity to complex firmly with this chelating agent at body pH conditions will undoubtedly be made. Since the advent of BAL (2, 3-Dimercaptopropanol) for combating arsenic poisoning, no

other organic complexing agent has proved of such value, although others, such as aurin tri-carboxylic acid for the elimination of beryllium (21), have been suggested from time to time.

An ingenious and novel use of a complexing agent for combating cyanide poisoning has been recently reported (22). Cyanideless vitamin B₁₂ (vitamin B₁₂^a, hydroxo-cobalamin) is capable of tightly coordinating with the cyanide ion in experimentally poisoned animals and thus preventing toxic symptoms and death.

Well-known reducing agents, such as ascorbic acid, have been reported experimentally at least to be effective prophylactically against a variety of toxic agents. For example, vitamin C was shown to function as effectively as CaEDTA against vanadium poisoning in animals (19), and this vitamin is reported (23) to reduce substantially fatal pulmonary edema and hemorrhage in animals inhaling ozone or nitrogen dioxide. Essentially complete protection against fatal ozone exposures in animals was afforded by a mixture of such reducing substances as glycuronate, cystine, and other similar substances that include vitamin C.

Two-carbon fragments administered as ethanol, acetate, and propanol have been reported to be capable of combating the highly toxic fluoracetate (1080) in animals (24), and they give promise of successful therapy for this poison. Cystine, methionine, and other sulfur-containing amino acids have been suggested as more general aids to the detoxifying capacity of the liver for protecting animals against the toxicity of 1,2-dichloroethane (25) and methylchloride (26).

Within the last few years, atropine has proved an effective antidote for parathion and other closely related organic phosphorous insecticides.

Air Sampling and Analysis

The development of valid threshold limit values goes hand in hand with the development of accurate procedures for sampling and analysis of the industrial atmospheric contaminants.

The Millipore Filter

Unquestionably, the greatest boon in recent years to such a development has been the introduction into the field of industrial hygiene of the Millipore filter (27, 28), known also as the membrane filter or molecular filter. This filter has an efficiency of sampling airborne particulates approaching 100 percent for all particle sizes of hygienic significance. The 150 μ thick paper of cellulose acetates and nitrates with 80 to 85 percent voids possesses a high dielectric constant and effectively attracts even noncharged particles of infinitely small size to its surface despite a mean pore size of 0.8 μ . Thus, the paper possesses a collection efficiency independent of the particle size of the aerosol. A limitation of the paper is that oils and tars clog the filter in a very short period of time, making it useless as a sampling medium for these materials.

Valuable use may be made of the property of the membrane to become transparent upon the addition of a limited amount of solvent (acetone, acetates, alcohols). This transparency permits the collected air sample to be directly counted under the optical microscope over a circumscribed, known area of the filter, thus providing a permanent dust mount that may be quantitatively analyzed.

Further advantage has been taken of the solubility characteristics of the Millipore filter by Fraser (29), who combined the high sampling efficiency of the paper and its solubility properties with electron microscopy to develop for the first time an absolute method of sampling and analyzing solid airborne particulates. In outline, the procedure consists of (a) collecting a sample of airborne particulates on the Millipore filter, (b) effecting transfer of the particles to a prepared electron microscope specimen screen after solution of the paper, (c) photographing the particles, and (d) determining the size distribution of the particles by visual measurement from their projection on a screen.

It is strongly urged that industrial hygienists take advantage of this powerful technique to explore the heretofore unsampled and unseen particles of industrial atmospheres and use such information to aid in the determination of their

industrial health significance. The results of such a study could well revise some of our concepts of the effective number of particles required to produce pneumoconiosis.

In the light of this and other recent developments, the Engineering Section of the Occupational Health Field Headquarters, Public Health Service, has undertaken an extensive reinvestigation of the entire field of dust sampling and measurement with the objective of developing improved generally acceptable methods that incorporate the advantages of these advances. Already the investigation has led to a promising use of the transparent properties of the Millipore filter, referred to above, as a dry, permanently fixed, dust sample for on-the-site use in plant or factory.

An automatic instrument which continuously records the mass concentration of dust in the atmosphere has recently been introduced (30). This instrument is based on the photoelectric measurement of forward-scattered light from solid or liquid aerosols and has a range from 10^{-3} to 10^{-2} $\mu\text{g./l.}$ in terms of dioctyl phthalate as 0.3μ diameter droplets. A further modification of this device is being undertaken by David Sinclair of the Johns-Manville Research Center in the development of an instrument which will indicate the size of the particulates as well as their concentration by electronically computing the ratio of backward and forward scattered light from the particles.

Another development in dust analysis techniques is the use of the electron microscope as an electron diffracting instrument. This technique is capable of exploring the surface of particles to the depth of approximately 0.05μ in respect to their crystallinity or lack of it. In conjunction with X-ray diffraction techniques which determine similar properties within the core of the particle, it may provide much useful information concerning the relation between the physical structure of dust and its physiological effects. At the Occupational Health Field Headquarters, such work is being done on the various forms of diatomaceous earths, and in Scotland, on various types of silica (31). Efforts along this line are expected to go far in helping elucidate the etiology of various types of pneumoconiosis.

Vapors and Gases

Developments in sampling and analysis in the highly individualized field of vapors and gases during recent years have yielded no new principle or device, but rather they have found application for many of the methods long used in other fields. The study of air pollution has given a sudden impetus in this direction. Among the recent innovations used in the air pollution field are the portable Venturi scrubber (32), which has proved satisfactory for sampling ammonia, nitrogen oxides, aldehydes and sulfur dioxide, freeze-out trains, large-capacity plastic bags, silica gel, and other solid absorbents (33).

For the analysis of organic pollutants, the infrared analyzer and the mass spectrometer are being explored rather widely. Chromatographic procedures have also aided in the confirmation of many often closely related organic substances present in the air.

Automation appears to be the only really new basic development in this field in recent years. This principle has been most successfully applied to the measurement of sulfur dioxide in the form of the Thomas Autometer (34). This instrument is especially useful in situations where round-the-clock measurements are needed, or with further attachments for signaling added, it may be used successfully for control of gaseous concentrations. Automatic analyzers have also been developed for halogen analysis, for carbon monoxide (35), and for other substances. It should be emphasized that such automatic recorders in their present state of development require careful standardization and repeated attention and maintenance to assure faithful recording of actual concentrations. Commercially available recorders vary widely in this respect. If original design has been good and the instrument carefully standardized and maintained, the saving to industry over the years far outweighs the relatively high initial cost. Increasing automation is foreseen for the coming years in this and related fields of analysis and control of air concentrations of contaminants.

It may seem unfortunate that many of the recent developments in the industrial hygiene field often involve the use of equipment that is

expensive and nonportable. Immobility, but not expense, is fast being overcome when the need demands. A mobile infrared analyzer has been designed (36) and a portable mass spectrometer as well (37). High cost, a factor necessarily associated with increased complexity and sensitivity, will be slower to be overcome.

Community Health Week, March 21-27

Community Health Week programs are recommended for March 21-27, 1955, by the United States Junior Chamber of Commerce in cooperation with the National Health Council.

Chapters of the Junior Chamber of Commerce have been asked by their national officers to name program chairmen for Community Health Week and to seek the aid of local health leaders. The program theme is "Know Your Community Health Resources."

Voluntary organizations are recommending that their affiliates provide the programs with cooperation and guidance. Basic health services will figure in programs where local public health units work with interested members of the organization.

Interested chapters will obtain a kit of aids from the national office. Suggested activities include health fairs and forums, special newspaper coverage, television and radio programs, exhibits, and school health projects.

Program leaders may wish to consult *Guide to Health Organizations in the United States, 1951*, by Joseph W. Mountin and Evelyn Flook. Public Health Service Publication No. 196. Available from the Superintendent of Documents, Washington 25, D. C. 30 cents.

Histoplasmin, Coccidioidin, And Tuberculin Sensitivity Among School Children In Two Texas Counties

By MICHAEL L. FURCOLOW, M.D.,
CHARLES F. FEDERSPIEL, M.A., and
HOWARD W. LARSH, Ph.D.

Although the general areas of histoplasmosis and coccidioidomycosis prevalence are well known, few studies of these diseases have been made in areas where both exist. Reactors to histoplasmin and coccidioidin, as well as tuberculin, among a group of Texas school children are reported in this study.

THE ENDEMIC areas of histoplasmosis and coccidioidomycosis appear to extend into Texas, the former from the northeast, the latter from the southwest. Observations on histoplasmin sensitivity in Texas indicate approximately 30 percent of the young adults are positive histoplasmin reactors. Among 209 lifetime residents of Texas attending the University of Chicago from 1946 to 1948, 61, or 29 percent, were found to be positive reactors to the histoplasmin skin test (1). Palmer's survey

Dr. Furcolow is medical officer in charge at the Communicable Disease Center's Kansas City Field Station, University of Kansas Medical Center. Dr. Larsh, professor and chairman of the department of plant sciences, University of Oklahoma, serves as special consultant in mycology at the field station. Mr. Federspiel, formerly statistician at the Communicable Disease Center, Public Health Service, Atlanta, Ga., is now graduate assistant, Institute of Statistics, North Carolina State College, Raleigh, N. C.

among student nurses yielded 21 positive reactors, 34 percent, of the 61 Texans tested (2). In a survey at Vanderbilt University, Christie and Peterson reported 7 positive histoplasmin reactors, 26 percent, among the 27 Texas residents tested (3).

These investigators made no effort to divide Texas into areas of histoplasmin sensitivity, but considered the State as a whole. The only report of a survey in a specific area is that of Forbes and Chang (4), who tested 441 infants and children in Dallas hospitals. This report showed a rise in sensitivity rates with age, reaching about 17 percent in the 12- to 15-year group. Since illness decreases skin sensitivity, it is probable that sensitivity among healthy children in this area would be higher.

In 1953, a survey of histoplasmosis and coccidioidomycosis in Texas was stimulated by the United States Army, which was concerned with the prevalence of fungus diseases in the area about Fort Hood where large numbers of men are trained. The location of Fort Hood and its relation to Bell and Coryell Counties are shown in figure 1. Tests were given only in Gatesville in Coryell County and Killeen in Bell County. These towns are at opposite ends of Fort Hood and are considered representative of the two counties. Landscape and climate are similar throughout the area.

Tuberculin tests were done also to furnish data to compare with similar surveys in other parts of the United States. In addition to the skin testing, a 35-mm. X-ray of the chest was obtained for each individual. A portable X-ray unit was used. The films were read by H. E. Smith of the Texas State Department of Health. Results of the X-ray survey are not considered in this paper.

Materials and Methods

The study was conducted between May 4-7, 1953. Tuberculin, histoplasmin, and coccidioidin tests were done simultaneously by intradermal injection of 0.1 cc. of the appropriate antigen. The tuberculin and coccidioidin tests

were placed on the volar surface of the left forearm, and the histoplasmin test was similarly placed on the right forearm. The injections were given by teams of three experienced persons, each using a separate set of syringes and needles and each injecting a single antigen. The tests were inspected 48 hours after injection, and measurements of the transverse diameter of erythema and induration were made by two experienced readers. Reactions were considered positive if the area of induration was 5 mm. or more in diameter without regard to erythema.

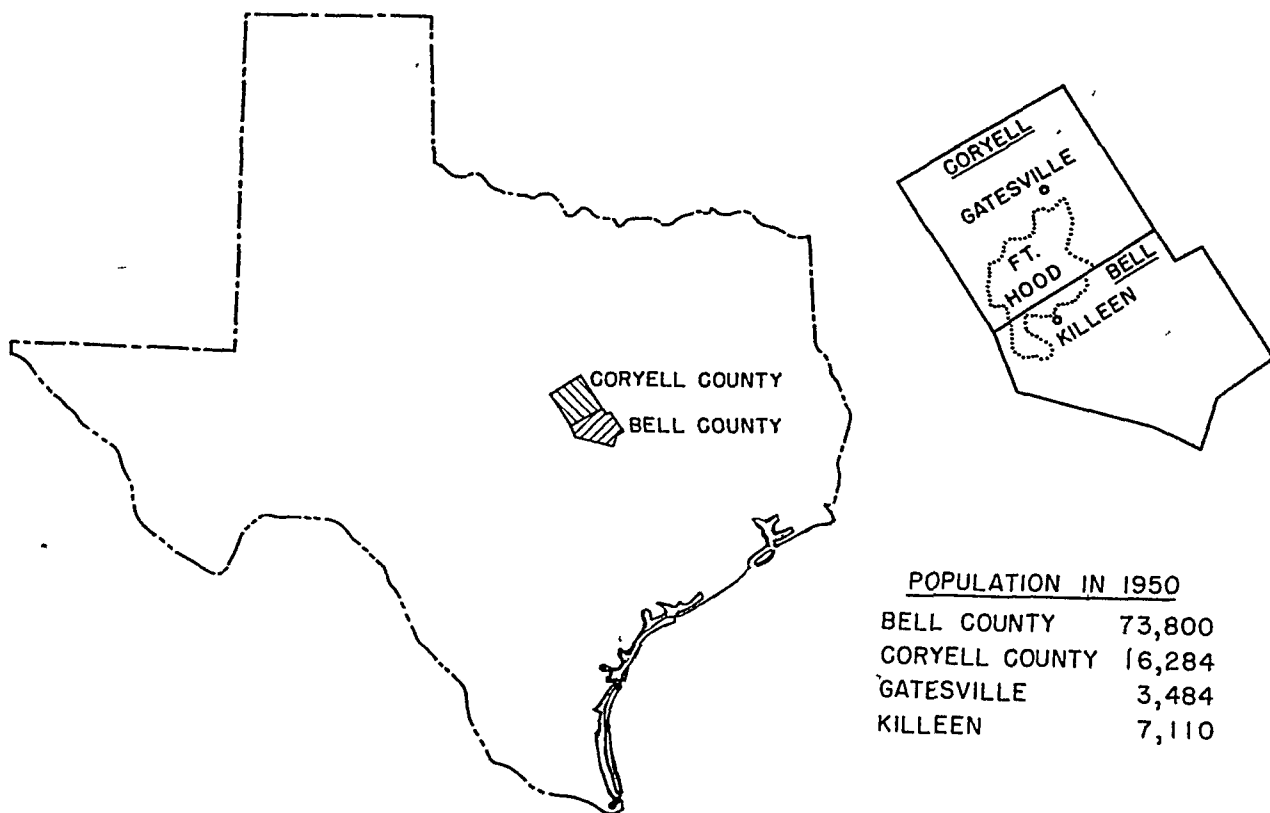

The tuberculin dosage was 0.0001 mg. in 0.1 cc. of diluent. The histoplasmin (lot IIKC-5) prepared and titrated by the methods of Shaw, Howell, and Weiss (5), was administered in a dilution of 2:1000. This histoplasmin and dilution are equivalent in potency to earlier products (1, 2). The coccidioidin was used in a dilution of 1:100.

A questionnaire, including parental consent form, was distributed to each student prior to the test. This form included identifying in-

formation, date of birth, sex, length of residence in Bell and Coryell Counties, and appropriate space for recording the results of the skin tests and the X-ray number. On completion of the survey these records were transferred to punchcards from which the desired tabulations were obtained.

Skin tests were given to 2,838 persons in the public schools at Gatesville and Killeen, Tex. Twenty nonwhite persons and 109 adults were eliminated from the analysis, leaving a total of 2,709. All of these children were considered in the analysis of the tuberculin results. Lifetime residents only were considered in analyzing the results of the histoplasmin and coccidioidin tests. Any person living at least 80 percent of his life in the Bell-Coryell County area was considered a lifetime resident. This criterion eliminated approximately half of those tested, since the children of army personnel at Fort Hood, a rather transient group, constituted a large proportion of the total school population. The data analyzed for histoplasmin and coccidioidin sensitivity, then,

Figure 1. Area of residence of persons given skin tests in Bell and Coryell Counties, Tex.

represents the indigenous population of Bell and Coryell Counties, essentially a rural area.

As used in the text, "rates" or "sensitivity rates" refer to the prevalence of positive reactors to the various antigens.

Results

Differences between schools. The number and percent of positive reactors to histoplasmin in the Gatesville and Killeen public schools are shown in table 1 and figure 2. Since the towns are approximately 30 miles apart, it was considered desirable to compare the sensitivity rates. As the rates for the two schools were approximately the same, for purposes of analysis, the results from the two areas were combined.

Table 1. Histoplasmin sensitivity prevalence among Gatesville and Killeen lifetime resident public school children, Tex.

Age nearest birthday	Gatesville			Killeen		
	Number tested	Number positive	Percent positive	Number tested	Number positive	Percent positive
6-7	79	10	12.7	67	3	4.5
8-9	141	14	9.9	131	15	11.5
10-11	129	20	15.5	148	24	16.2
12-13	101	23	22.8	139	40	28.8
14-15	96	20	20.8	109	37	33.9
16-17	53	22	41.5	115	39	33.9
18-19	22	10	45.5	53	20	37.7
Total	621	119	19.2	762	178	23.4

Tuberculin sensitivity. Table 2 and figure 3 show the number and percent of positive reactors among the 2,709 white children tested. The rates were relatively low, rising from 1.8 in the 6- to 7-year age group to 6.1 in the 16- to 17-year age group. There was a clear-cut rise in rates with age. The overall rate was 4.0 percent. Four of the 18 Negro children tested were positive to tuberculin.

Histoplasmin sensitivity. The data on the frequency of positive reactions to histoplasmin are given in table 3 and figure 3. These data, confined to the 1,383 white lifetime residents tested, show progressively increasing rates of

Figure 2. Prevalence of histoplasmin sensitivity among lifetime residents in Gatesville and Killeen schools, Tex.

sensitivity with age. The 6- to 7-year age group had 8.9 percent positive and the oldest age group, 18- to 19-year olds, had 40.0 percent positive reactors. The overall percentage of positive reactors was 21.5 percent.

Coccidioidin sensitivity. Few of the lifetime residents of Bell and Coryell Counties reacted to this antigen (table 3 and fig. 3). Although the rates were low, they were based on a relatively large sample and show a tendency to increase with age, from less than 1 to almost 3 percent. The low rates of sensitivity

Table 2. Number and percent positive tuberculin reactors among white school children in Bell and Coryell Counties, Tex.

Age nearest birthday	Number tested	Number positive	Percent positive
6-7	325	6	1.8
8-9	578	16	2.8
10-11	581	27	4.7
12-13	448	19	4.2
14-15	379	17	4.5
16-17	279	17	6.1
18-19	119	7	5.9
Total	2,709	109	4.0

to coccidioidin suggest that coccidioidomycosis is not endemic in this region of Texas. A number of coccidioidin reactors were noted among the "nonlifetime" residents. These occurred among persons whose major residence had been in western Texas.

Sex differences in histoplasmin sensitivity. The positive reactions among males and females are shown in table 4 and figure 4. The overall frequency was higher among males than females (26 versus 17 percent). This has been noted in other surveys (6, 7). However, the rates were essentially equal up to the 12- to 13-year age group. Another difference between the male and female rates was the failure of the female rates to show a marked increase with age beyond the 10- to 11-year group. In fact, the rates for females above this age were almost constant. The only rise occurred in the 18- to 19-year group, where only 29 girls were tested. The reasons for these sex differences are not known.

Cross reactions. Cross reactions in patients tested with histoplasmin and coccidioidin have been reported (8). The comparison of the size of the reaction to histoplasmin and to coccidioidin in the same children is shown in table 5. It appears that some of the coccidioidin reactions were cross reactions. This was indicated by the number of children who showed a smaller reaction to coccidioidin than to histoplasmin.

Table 3. Number and percent positive reactors to histoplasmin and coccidioidin among lifetime residents of Bell and Coryell Counties, Tex.

Age nearest birthday	Number tested	Histoplasmin		Coccidioidin	
		Number positive	Percent positive	Number positive	Percent positive
6-7--	146	13	8.9	1	0.7
8-9--	272	29	10.7	3	1.1
10-11--	277	44	15.9	3	1.1
12-13--	240	63	26.3	7	2.9
14-15--	205	57	27.8	5	2.4
16-17--	168	61	36.3	3	1.8

Total...	1,383	297	21.5	24	1.7

¹ One child in this group was tested with histoplasmin but not with coccidioidin.

Figure 3. Prevalence of histoplasmin and coccidioidin sensitivity among lifetime resident school children, and of tuberculin sensitivity in all school children, Bell and Coryell Counties, Tex.

Many of the coccidioidin reactions were specific reactions and not cross reactions. This was clearly shown in the 52 children who reacted to coccidioidin but were negative to histoplasmin. Of these, 14 were positive reactors. In 13 other children, the reactions to coccidioidin were larger than to histoplasmin.

Discussion

Although the purpose of this survey was to determine the prevalence of sensitivity of histoplasmin and coccidioidin, the tuberculin rates also proved interesting. The tuberculin rates among children in this rural area of Texas were surprisingly high. In comparing rates obtained under similar circumstances with the same lot and dose of tuberculin, the Texas rates were found to be twice as high as those among the suburban children in the vicinity of Cincinnati, Ohio (6). While the Texas rates appeared

to be about half as great as rates observed in Kansas City, Mo., (6) they were still surprisingly high for a rural area. These rates were not accounted for by the presence of large numbers of Mexican or Latin American children, since less than 5 percent of the children tested were of such origin. The presence of Negroes did not complicate the picture, since they were not included in the analysis.

Table 4. Histoplasmin sensitivity prevalence according to sex among lifetime resident school children of Bell and Coryell Counties, Tex.

Age nearest birthday	Male			Female		
	Number tested	Number positive	Percent positive	Number tested	Number positive	Percent positive
6-7-----	73	7	9.6	73	6	8.2
8-9-----	138	14	10.1	134	15	11.2
10-11-----	149	22	14.8	128	22	17.2
12-13-----	118	38	32.2	122	25	20.5
14-15-----	103	36	35.0	102	21	20.6
16-17-----	76	42	55.3	92	19	20.7
18-19-----	46	22	47.8	29	8	27.6
Total--	703	181	25.8	680	116	17.1

The histoplasmin sensitivity rates also deserve comment. While the exact prevalence of histoplasmosis in Texas has never been determined, a number of cases have been reported from Veterans Administration hospitals, Army hospitals, and other sources.

Preliminary studies mentioned earlier (1-4) had not indicated such a high prevalence of sensitivity among lifetime residents. The fact that 40 percent of the children were sensitive at the age of 18 certainly points up the problem for physicians in this area. It might also be appropriate to mention that *Histoplasma capsulatum* was isolated from 1 of 30 soil samples taken from the Fort Hood reservation. Also, this fungus has been isolated from the soil obtained from north eastern Texas near the Arkansas-Louisiana border.

Cross reactions between fungus antigens appear to be common. This is illustrated by the results of Smith and associates (8) showing cross reactions in humans between coccidioidin and histoplasmin. Also, cross reactions be-

Figure 4. Prevalence of histoplasmin sensitivity by sex among lifetime resident school children of Bell and Coryell Counties, Tex.

tween histoplasmin and blastomycin in humans have been reported (6). There is some evidence of cross reactions between histoplasmin and coccidioidin in these studies as evidenced by the finding that 45 persons reacted to both tests whereas, on a chance basis, only 13 reactions would have been expected. There was also evidence of specific sensitivity to both antigens.

Summary

Histoplasmin, tuberculin, and coccidioidin skin tests were made on 2,838 persons in Bell and Coryell Counties, Tex. Tuberculin sensitivity was found to be relatively high for a rural area. Histoplasmin sensitivity among lifetime resident school children was found to increase with age, reaching 40 percent positive in the 18- to 19-year age group, indicating a prevalence of sensitivity somewhat higher than had been expected for this area. The coccidioidin prevalence was low, which seems to

Table 5. Comparison of the size (in millimeters) of the histoplasmin and coccidioidin reactions in the same child (induration only)

Histoplasmin								
Coccidioidin	Size	0	1-4	5-9	10-14	15-19	20 and over	Total
	0	2,135	32	326	181	14	3	2,691
	1-4	38	1	15	4	3	0	64
	5-9	10	1	10	12	5	0	38
	10-14	2	0	4	5	0	1	12
	15-19	1	1	0	1	1	0	4
	20 and over	1	0	5	1	0	0	7
	Total	2,187	38	360	204	23	4	2,816

indicate that *Coccidioides immitis* is not endemic to this area.

It would appear from the known geographic distribution of histoplasmin sensitivity that the rates of reaction probably are even higher as one moves eastward from this area. Physicians in the entire area should therefore be alerted for possible cases of histoplasmosis. As mentioned above, the cases of histoplasmosis which have been reported from Texas have been confined to the large medical centers and Veterans Administration hospitals. Since the infection is generally more common in rural areas, it is probable that large numbers of cases are being missed.

The low rate of coccidioidin sensitivity in Bell and Coryell Counties is noteworthy since the endemic area of coccidioidomycosis has not been too well defined in Texas. It is well known that western Texas and the Rio Grande River Valley are in the endemic area since cases have been reported in these locations (9). However, the extension of this area to the north and east has not been well delineated. From these studies it appears that this infection is not common in the central area of Texas around Fort Hood. The reasons for the occurrence of almost 2 percent coccidioidin reactors among lifetime residents are not evi-

dent. It might be due to the presence of only a few spores in the soil or to unknown visits into the high area of sensitivity. It should be remembered also that the prevailing winds blow from western and southern Texas over this area and might conceivably disseminate the spores of *C. immitis*.

ACKNOWLEDGMENTS

The authors are indebted to Florence B. Seibert of the Henry Phipps Institute of Philadelphia, Pa., for the purified protein derivative (PPD-S) tuberculin and to Charles E. Smith of the University of California for the coccidioidin.

A cultural anthropologist suggests that examination of technological development programs of the past 20 years reveals certain empirically derived principles which have stood the test of time and which, if followed in setting the limits of community development programs, will greatly increase the chances of success.

Guidelines to Community Development Programs

By GEORGE M. FOSTER, Ph.D.

DURING the spring term of 1954, I participated in an informal discussion group in the University of California's School of Public Health at Berkeley.

This group, which met for six 2-hour sessions over a period of 12 weeks, was composed of faculty members and foreign and native North American graduate students, most of whom had had field experience in areas other than the United States. The foreign students—there

were four—were members of international public health organizations active in Brazil, Ceylon, and Iran. The United States participants based their remarks on their various work experiences in China, India, Southeast Asia, Mexico, El Salvador, Puerto Rico, Peru, and Chile.

The general topic of the meetings, which was never formally stated, had to do with the manner in which cultural factors bear upon the success or failure of community development programs. Though the group was primarily interested in questions of public health, it soon became apparent that public health could not be treated as an isolated problem and that the community itself must constitute the real focal point of interest.

There emerged from the deliberations of the group the conviction that, although precise rules for successful work in any geographic area, or any limited disciplinary field, could not be laid down, there were, nevertheless, certain general principles which seemed to hold good in most situations. These cannot be thought of as "principles" in the scientific sense of the word, but rather in the sense of empirically derived rules which, if borne in mind by field personnel, would contribute to the success of their programs. These rules, which constitute the greater part of this report, are in no sense new or original. They represent, rather, a summary of field experience of the discussion group, sup-

Dr. Foster, the former director of the Smithsonian Institution's Institute of Social Anthropology, is visiting professor of anthropology and lecturer in public health at the University of California (Berkeley). Also a member of the Health Committee on Foreign Operations Administration programs, he became active in the field of public health after making a preliminary analysis of the bilateral health programs in Latin America for the Institute of Inter-American Affairs and joining the IIAA evaluation team headed by Dr. Wilton L. Halverson. Some contemporary Latin American cultural problems and their relationship to the planning of public health programs have been summarized in the report of Dr. Foster's section of the IIAA survey as "Use of Anthropological Methods and Data in Planning and Operation." This report was published in Public Health Reports, September 1953, p. 841, as one of the Servicio evaluation series.

Members of the Discussion Group

Foreign students:

- Nilo de Brito-Bastos, M.D., Servicio Especial de Saúde Pública, Brazil.
Siri Dangalle, Unesco-Ceylon Fundamental Education Project, Ceylon.
Hortensia de Hollanda, Ministry of Public Health, Brazil.
Garegin Saroukhanian, Public Health Cooperative, Foreign Operations Administration, Iran.

University of California faculty members:

- Jessie M. Bierman, M.D., professor of maternal and child health.
George M. Foster, visiting professor of anthropology and lecturer in public health.
William Griffiths, associate professor of public health.
Jerome Grossman, associate in public health.
Ann Haynes, visiting professor of public health education and chief, bureau of health education, California State Department of Public Health.
Ruth Huenemann, lecturer in public health nutrition.
Sarah Mazelis, associate in public health.
Edward S. Rogers, M.D., professor of public health and medical administration.

United States students:

- Ernest Bertellotti, Dorothy Craig, John Hayakawa, Ellen James, Virginia Pence, and Edward Riggs, M.D.

plemented by the conclusions contained in a series of papers and books which have appeared over the past 15 years. They may be thought of as a "practical," "rule-of-thumb," or "working-man's" guide rather than as a theoretical statement of the principles of culture change.

Since general theoretical principles are not dealt with at length here, it is desirable to state more precisely the limits of the problem as considered by the group. Early in the discussion it was agreed that the concept of culture constituted the key to the problem. Simple definitions of culture were accepted: the common way of life shared by the members of a group, consisting of the totality of tools, techniques, social institutions, behavior patterns, attitudes, beliefs, motivations, systems of values, and the like—or, to use Linton's short definition (1): behavior and the products of behavior of a human group.

Two basic aspects of culture were found to bear directly on the problem.

First, it was agreed that any culture should be thought of as a functional, integrated whole, and not as a haphazard collection of customs and habits. If the analogy is not carried too far, a culture could be compared, it was felt, to a biological organism, in that each of its parts is related in some way to all other parts. Each part fulfills a definite function in relationship to the other parts and contributes to the normal functioning of the culture as a whole. Each part, in turn, draws upon all the other parts in some way for its own continued existence, and its growth and development are dependent on corresponding growth and development in the culture as a whole.

To illustrate this concept of integration in terms of public health, it was pointed out that preventive medicine and sanitation projects are not isolated parts of the life of a people. They are related to education, economic productivity, distribution of income, social security, municipal administration, philosophical and religious premises, and a host of other things. Changes in the level of health in any given region may result from improvements or changes in these aspects of culture. Conversely, changes that can be brought about by planned action are limited by, and dependent on, the changes that simultaneously are occurring, or can be made to occur, in these related aspects.

Second, the group recognized that all cultures are capable of change and that all cultures are constantly changing, whether the pace be rapid or slow. It was agreed that there are definite, though unfortunately imperfectly understood, rules of human behavior which govern the processes whereby changes occur. In general, there appear to be two basic types of culture change: One may be called "spontaneous," or perhaps "evolutionary," in that the change happens without the conscious efforts of individuals or groups, and the other may be called "directed," or "guided," in that group planning and action leads to goals which, it is thought, will promote a happier, healthier, better educated, and independent society. All community development work, regardless of type, clearly falls in this second category.

Obviously, directed culture change is, in the broad sense, not new. Wars of conquest, economic development of societies and geographic regions, missionary activities, democratic community organization for civic ends, the efforts of the fathers of the American Revolution, all fall into this category. But, in recent years, certain types of guided culture change have swung into sharper focus. Though the term is now officially obsolete, "Point IV type programs" conveys the idea in fewest words. Regardless of sponsorship, the thought is that through a combination of outside and self help the economic and emotional security of those people of the lower social and income strata, wherever they may live, may be advanced. The problems often are more acute in those countries of slight economic development, as contrasted with the more highly industrialized areas, but the question seems to be one of degree and not of kind. One of the most interesting facts to develop from the discussion group was that the problems—and the means of attacking them—that applied to foreign countries were believed by those who had worked principally in the United States to reflect local situations to a surprising extent. That is, the rules for successful work in, let us say, Latin America, are also good rules to apply in the United States.

A particularly difficult question underlying directed culture change programs is that of "values." Who determines the needs and rights of a people? Who decides what is best, what should be done, what habits should be changed? In general, it was agreed that all such goals should be a function of the culture in question and not a reflection of the goals and attitudes of the outside countries sending the specialists. Though the discussion group considered the matter of values, for purposes of outlining rules of work, the question was begged. It was assumed that through research and careful thought, and through consultation and planning among all interested governments, goals could be determined which are consistent with the felt needs and aspirations of the people to be affected.

The problem then became one of determining the most practical methods to be used in field

operations. There was general agreement that the 12 rules listed and discussed below, although not constituting an exhaustive list, seem to hold true in a majority of cases.

The 12 points suggested do not constitute a guide to any specific type of program—health, agriculture, or education. The list does not include all the things that the program planner and director should bear in mind, nor do all of the points necessarily apply in a given situation. Any specific problem must be thought of as a more or less unique phenomenon, although it will, of course, have much in common with other similar problems. Many of the general principles suggested here will apply, but they are no substitute in themselves for thorough and accurate community analysis before a program is completely planned and initiated.

1. *Know the culture in which work is to be done*

Since the idea behind directed culture change is to change or add to something already in existence, it is apparent that we must know what the "something" is before an attempt to change it is considered. There are, unfortunately, no short cuts to learning a culture. It is work that takes time and patience. And, in most cases, it is best done by a trained cultural anthropologist or sociologist who is familiar with the projected action goals and who bears in mind the data needs of the administrator but who, nevertheless, ideally works toward a full picture of the culture. This is a point that is sometimes hard for the administrator to understand. The reason is that in the beginning it is often impossible to know what significant factors bear on any concrete project. An obscure point in the prestige complex of a people may, for example, hold the key to the successful introduction of pit privies; or the supernatural beliefs of a people with regard to seed corn may be the determining factor in preventing the introduction of a hybrid variety.

Although at the present time there is great need for thorough basic studies in all cultures, the problem of acquiring the necessary insight will become easier as time passes and knowledge is accumulated. Although each country, and

each village, is different in some ways from all others, nevertheless, all villages in an area and most countries in a region share a majority of their basic culture patterns. This means that when a series of selected studies has been completed it becomes possible to infer a great deal about the basic patterns in other unstudied areas; that is, the basic underlying patterns hold true over wide areas. Once these patterns are worked out, the research problem then becomes one, in any specific locality, of isolating the specific factors that are unique to the locality, and relating these factors, as well as the underlying patterns, to the immediate project.

For example, cultural anthropologists and rural sociologists have, over the past 25 years, made a series of basic studies of contemporary Latin American culture. Although the picture is far from complete, enough of the basic patterns have been isolated so that when a specific project was outlined it was possible to acquire significant data in a surprisingly short time because the field workers built on the accumulated scientific capital of 25 years of work. Hence, if we are correct in assuming that directed culture change programs are just beginning a period of enormous expansion, it is particularly important to urge that active support be given to long-range basic cultural analyses.

2. Select the site of operations with extreme care

Paradoxical as it may sound, at this stage of our knowledge it is usually wise to select a community which, through past progress and a progressive spirit, gives indications of future progress. All too often, program sites have been selected on the basis of the absolute poverty of a people, of their crying need for help. To select communities that are somewhat better off, it is argued, would reflect a fundamental disregard for humanitarian principles. Communities in all parts of the world tend to fall into progressive and conservative categories. The factors that underlie these differences are not well understood, but it does not take extensive investigation to determine, in any locality, the order of rating of all groups. Usually, the people of a community know where they themselves fall. Factors which may often underlie a progressive community, and which

therefore make it a favorable one in which to commence work, include a relative lack of social cleavages, a reasonably stable economic basis, the characteristics of a population that is not too marked by transients or one in which political dissensions are not extreme, and so forth.

So little is known about the requirements for successful directed culture change that failure may result, even under apparently ideal circumstances. Too many otherwise sound projects have been doomed to failure before they were begun simply because the most difficult site possible was selected. Once a certain success has been obtained in a community, once the confidence of field personnel to cope with the local situation is established, once the specific problems of operation of a given locality are solved, then it is possible to work in the socially and economically more retarded communities. Often the successful example of a progressive village will spell the difference between success and failure in adjacent neighborhoods.

3. Pay first attention to selection of the program staff

The delegating of authority to individuals temperamentally and scientifically unsuited to the work they are to perform has caused as many failures, perhaps, as any other single factor. It is better not to start a program than to attempt to push it through with unsuitable personnel. Perhaps failure to pay adequate salaries is the biggest single shortcoming in selection of personnel. Reasonably high pay is essential for at least two reasons: to attract persons of sufficient education and intelligence to understand thoroughly the problems involved; and to give personnel sufficient prestige and status within their own bureaucratic organization so that they identify themselves with the goals of top level management, rather than letting them feel that they are underpaid and unesteemed flunkies. Personnel must command the respect equally of their superiors and of the people among whom they work.

4. Regardless of long-range hopes, start with a simple project that shows obvious results in a short time

It is difficult, if not impossible, to maintain unflagging enthusiasm on the part of local peo-

ple if results are not quickly apparent to them. The local leaders who identify themselves with a new program, and who push it among their fellows, threaten their own position in the community when they cannot demonstrate results within a reasonable time. Frequently, the best local cooperators have been lost, and perhaps their active opposition has been incurred, simply because results could not be shown or perhaps because outside promised aid, on which they counted, was slow in making its appearance.

It is quite legitimate to use "bait" projects if necessary—projects not directly associated with long-range goals, but which represent felt needs of the people and which arouse their interest. Whatever the initial projects, avoid those heavily charged with emotional factors. Since the emotional charge varies enormously from culture to culture, it is apparent that sound basic knowledge of the local group is essential to avoid possible mistakes here.

5. *Take advantage of the pragmatic nature of people*

This rule is closely related to the preceding one. The most striking fact to emerge in recent studies of directed culture change is that people are pragmatic to an unexpected extent. If with their own eyes they can see results that they recognize as beneficial to them, regardless of their understanding of the reason, regardless of tradition and superstition, regardless of factors that might otherwise cause them to hold back, most people will give up the old and adopt the new. The problem, of course, is the means of convincing people that something is beneficial to them.

In general, a striking demonstration of the new is a positive way of changing behavior. In some areas this is easy. Malaria and yaws control programs, for example, quickly convince. Smallpox control is more difficult to prove, since success is less spectacular. However, if a striking demonstration can be made in any area of culture, the confidences established in the innovators may often be utilized to effect changes in areas where demonstration is difficult, if not impossible. Or, in other words, proof in one area will lead people to take other statements on faith—faith that would not

be forthcoming without the original demonstration.

In one South American city, for example, the visual success of an emergency whooping cough inoculation program in stemming a threatened epidemic was sufficient to assure the active cooperation of mothers in a subsequent BCG tuberculosis campaign.

But simple, unspectacular demonstrations are also important in many projects. To illustrate: If it is desired to introduce a new food, it is essential to show by demonstration all the steps in its preparation. Food and its preparation diffuse as a unit. It is not sufficient to give people the new food and expect them to cook it according to one of their traditional ways.

6. *Don't ask people to do anything they fear may threaten their already narrow margin of material security*

The poorest farmer is not the one who will first try an improved seed, no matter how desperate his need. However precarious his situation, from past experience he at least knows the dangers and limitations inherent in his traditional methods; he knows what to expect and can lay his plans accordingly. He is not apt to risk this narrow, but predictable, margin of known security by taking a chance on the say-so of an outside stranger. The poorest and busiest mother with the most sickly children is not the one who can afford to stand in line long hours in a health clinic to have a child examined. In general, most progress will be made if a target group is selected that lies somewhere between the lowest and highest extremes of social and economic status. Once progress is demonstrated with this target group, the obvious benefits will diffuse both upward and downward.

7. *Think in terms of the economic and social potential of the community—not in terms of an ideal program*

In the long run, any new program will have to be carried in large measure by the people themselves. Overplanning, in the sense of the "best" program for, let us say, a small rural center, may burden its citizenry with economic and maintenance commitments which would only be consistent with the growth of a prosperous industrial community.

8. *Aim at integrated, broad programs*

Insofar as is possible, it is usually advisable to think in terms of total community development rather than in terms of a single field of endeavor. In the first place, broadening a program spreads capital investment more widely, thus lowering unit costs. In the second place—and even more important—no type of project operates in a vacuum. A sound health program, as pointed out, depends on good agriculture, education, honest and efficient civic government, and an economic surplus. Good farming depends on healthy and informed workers, and good government requires all of these underlying factors, and many more. There are, admittedly, many practical problems that interpose themselves between the desire for a broad program and its realization; and special local situations will sometimes mean that it is impossible or unnecessary to conduct a program on a broad basis. Nevertheless, as a general goal, this aim seems valid.

9. *Follow the right sequence in a program*

All community programs represent continuums in time. Each project of a major program must be adapted both to the other projects and to the general cultural setting, not only as of a given date, but also in terms of time depth. When the factors that bear on the relationship of a given project to other projects, and to the culture at large, are known, then its place in the sequence of projects can be better determined. For example, reading rooms and books should not be introduced into a community until such time as the ability to read has become an accepted value by at least a significant part of the group and until this part is clamoring for knowledge. Or again, undue stress on preventive medicine in public health programs will meet with little success until the immediate felt need of curative medicine is at least partially satisfied.

10. *Use existing community leadership whenever possible*

In general, the evidence indicates that existing community leaders working through existing community institutions, such as church, government, school associations of fathers or mothers, and the like, constitute the most effective

way to get action. Individuals who are poorly adjusted to their own cultures and whose discontent often quickly brings them to the side of outside innovators, will not, in most cases, be leaders who can aid a project. It is important to recognize the distinction between formal and informal patterns of leadership. Both patterns have their place in community development. Unfortunately, our knowledge of the structure of leadership in many parts of the world is rudimentary and much research on this problem seems indicated.

11. *Avoid local commitments against a project*

Every effort should be made to obtain the cooperation of as many people as possible before they go on record as opposing the project. There are almost always people in each community who are only too anxious to express themselves negatively, particularly if their advice has not been asked. Once committed publicly against a project, it is very difficult for them to change their stand, since it will mean a possible loss of "face." If positive cooperation cannot be elicited, at least try to promote a neutral attitude.

12. *Require payment for certain services*

A great deal of evidence suggests the wisdom of charging at least a token sum for many types of health, agricultural, and educational services. In many parts of the world, the fact that something is given away carries a strong implication of worthlessness. Even a small payment, adjusted to the ability of the recipient to pay, will often create an awareness of value and will elicit cooperation, where the same service or item given free would be ignored or thrown away. To illustrate: In an agricultural extension program in a South American country, it was found that if fruit trees were given to farmers, the farmers usually failed to plant them. When a small charge was made for the same trees, the farmers' interest was heightened, more trees were planted and cared for, and the overall results were more satisfactory.

Dining Car Sanitation in the United States

By WILLIAM H. MEGONNELL, M.S., and EDMUND C. GARTHE, C.E., M.P.H.

ONE of the most striking features about dining cars is that while they resemble restaurants they are, at the same time, very dissimilar. True, the dining car is simply a special kind of restaurant—a restaurant on wheels, not differing in other essentials from other establishments where food is prepared and served. Dining cars and restaurants purchase the same kinds of food and prepare and serve them in the same manner, employing the same kinds of people. However, the one essential difference—mobility—creates problems which are peculiar to dining cars. It is one thing to supply and operate a stationary restaurant and quite another to supply and operate a restaurant that traverses hundreds of miles of railroad track.

A dining car superintendent has to anticipate and cope with seasonal peak loads and plan for large special movements of passenger traffic, such as are associated with military or emergency activities. Add to this the possibility of breakdowns, accidents, and other contingencies, and it is apparent that a sizable pool of fully equipped cars and trained personnel must be kept in reserve for such circumstances. This

is tantamount, if it can be imagined, to a large restaurant chain's keeping idle several expensive restaurants which are opened for business only during occasional rush periods.

The relationship between travel and the spread of disease has been recognized for centuries. Many hundreds of thousands of people in the United States travel on trains every day. About 80 million meals are served in dining cars each year. Thus, the fundamental rules of food service sanitation for preventing the spread of disease apply equally to dining cars and restaurants.

Since dining cars are rolling restaurants which cross State boundaries, their sanitary control is clearly a Federal responsibility. Indeed, it would be almost impossible to control them otherwise. The multiplicity of State and local health requirements and the variations in inspections by different health departments would result in intolerable confusion to carrier companies. More important, attempts by a State or local health department to follow through on an inspection or to investigate a disease outbreak attributed to food or drink consumed on a diner would be so complicated, after the conveyance had traveled into another State, that the efforts largely would be futile. Even negotiations between a health department and a railroad company would be difficult and complicated if the carrier's headquarters were located in another State (1).

Interstate quarantine authority was given to the Public Health Service by an act of Congress approved February 15, 1893 (2). This action was taken because of the continued presence of yellow fever during the summer months in the southern States. It was believed that the interstate railroads were a big factor in

Mr. Megonnell, senior assistant sanitary engineer, Interstate Carrier Section, General Engineering Branch, Division of Sanitary Engineering Services, joined the Public Health Service in July 1951. Mr. Garthe is the regional engineer for Region III of the Service (Washington, D. C.). At the time he was chief of the former Interstate Carrier Branch, Mr. Garthe coauthored with Howard W. Chapman, the article "Sanitation Aboard American Flag Vessels," published in Public Health Reports, October 1952, p. 963.

transmitting the disease from one State to another.

The interstate quarantine regulations, promulgated under the 1893 act and effective September 27, 1894, were the first concerted attempt to deal with the interstate spread of disease. These regulations have been revised and amended from time to time, most recently in 1951, to take cognizance of new developments in health and technology (3, 4).

Development of Diners

In the earliest days of railroading, before the advent of the diner, passengers had to depend largely on their own ingenuity for sustenance during a journey. The hardier and more resolute individuals risked the "eat-and-run" meals available at station stops; the less hardy or more discriminating resorted to carrying "shoebox" lunches. Both resources had obvious disadvantages. The food available at many stations in those days was generally stale and unsavory, while cleanliness and sanitation were questionable, at best. Lack of refrigeration and the presence of dust, soot, and insects often destroyed the appetite—and sometimes the health—of those who carried their lunches. The remaining choice, which many passengers took, was to go hungry (5).

Eastern railroads improved the intolerable situation by better surveillance and supervision of existing establishments. In the west the problem was more basic than amelioration because there were few restaurants of any sort. However, in 1876, a young railroader with the firm conviction that the traveling public would appreciate and generously reward anyone who began the reformation of the lowly railroad eating house established the first of what were destined to become famous station restaurants (6). Some of these exist today. His high standards of cleanliness, excellent cuisine, efficiency, and service developed into an art which became the model for such establishments and doubtless influenced the quality of railroad dining service.

Technological progress of the railroads and demands of the speed-conscious public who objected to meal stops made inevitable some form of dining service en route. The first recorded at-

tempt to provide food aboard trains was made in 1862 by the Camden and Amboy Route, which converted a baggage car into a diner for use on its Washington express. The following year, the Philadelphia, Wilmington & Baltimore Railroad remodeled two day coaches for service as diners between Philadelphia and Baltimore. In 1867, George M. Pullman introduced "hotel cars," which were sleeping cars equipped with kitchen and dining facilities. The first full dining car was built by Pullman in 1868 for the Chicago & Alton Railroad (5).

Regarded at first as somewhat of a curiosity, dining cars were enthusiastically received by the traveling public, but they did not come into general use until the late 1800's, no doubt as a result of the intense railroad competition during that period. Dinner in the diner became as much a part of the romance of railroading as the familiar click of the wheel on the track. As the shoebox lunch gradually disappeared the dining car became the real heartbeat of the train and the showcase of the railroads.

Although the Public Health Service was charged with the control of sanitation on dining cars, other important duties and budgetary and personnel limitations made an aggressive program impossible. So for many years governmental inspection and supervision of sanitation on dining cars were sporadic. All commissioned officers of the Service were under orders to inspect dining cars while en route on trains on official business; occasionally, surveys of entire roads or of all dining cars entering a railroad center were conducted as the result of a complaint; but there was no continued, routine program for such work.

However, from the beginning the railroads set high standards for their dining car service. Gleaming tableware, spotless linen, immaculate and courteous waiters, gracious stewards, and tasteful decor—all of these contributed to the dining car's unique atmosphere.

The War Emergency

During and immediately after World War II, uncontrollable emergency conditions precluded the exactitude formerly devoted to the comfort of the traveling public. Warworkers and servicemen were on the move, often with their fami-

lies, traveling from one section of the country to another on an unprecedented scale. The heavy increase in wartime rail travel came when railroads were unable to purchase new equipment. At the same time well-trained employees were off to war or to more lucrative jobs, forcing dining service managers to employ large numbers of untrained personnel.

This Nation could ill afford to waste manpower sick abed—or buried—as a result of foodborne or other disease. The increased significance of the Public Health Service's responsibility to prevent the interstate spread of disease during the war emergency led to a major intensification of its railroad sanitation program. A large portion of the country at war was eating from the dining car's "hands," and these "hands" had to be kept clean.

As one of the first steps in discharging its increased responsibility, the Public Health Service in 1942 prepared the "Sanitation Manual for Land and Air Conveyances Operating in Interstate Traffic" (7) to provide public health and railroad workers with necessary information upon which to base their activities under the interstate quarantine regulations.

Mobile bacteriological laboratories of the Service toured the country. As part of their duties the laboratory staffs examined milk and water supplies used aboard dining cars and made swab tests of eating and drinking utensils to ascertain the adequacy of dishwashing and sanitizing methods aboard conveyances. Also, during this period, studies of the sanitation problems peculiar to dining car operation were being conducted by the Service.

After the war the railroads desired to reestablish, and even to improve, the traditional, pre-war, high-quality standards of their dining service. To aid them in their efforts, and to enhance its activities in the prevention of disease borne by food, milk, and water, the Service further expanded and intensified its dining car sanitation program. Additional personnel were employed and trained as inspectors, and liaison with railroad associations, individual companies, and designers and builders of dining cars was strengthened.

As a starting point in their program many railroads began planning the construction of new cars, and others undertook reconstruction

of old ones which had been so overworked during the war. It had long been recognized that the plant where a conveyance is built or rebuilt is one of the best health control points. Placing greater emphasis on construction, Service personnel began to furnish consultative and inspectional services to designers and builders of railroad passenger cars.

One large company, in 1914, requested advice in designing new equipment and rehabilitating old cars. Thus was born the Service's plan-review program, under which plans for construction or major repair of conveyances are examined and are either approved or returned to the carriers with recommendations for changes. Under provisions of the interstate quarantine regulations, carriers are required to submit such plans or to arrange for Public Health Service inspection during construction.

In 1951, with the cooperation of the Joint Committee on Railway Sanitation of the Association of American Railroads and railroad car-building firms, the Public Health Service published the "Handbook on Sanitation of Railroad Passenger Car Construction" (8), which contains guides for incorporating sanitary provisions into the design or construction of railroad passenger cars and the reconstruction of existing cars.

Nowadays, before accepting delivery of a conveyance, a carrier usually specifies that the builder must obtain a Certificate of Sanitary

Construction from the Public Health Service. This certification, which shows that dining cars have been constructed or reconstructed in compliance with the interstate quarantine regulations, is mutually advantageous to the carrier and the builder. The builder is protected from future criticism; the purchaser is assured that his conveyance has been constructed in accordance with high standards which reflect decades of sanitary engineering knowledge. Of 230 new and rebuilt railway conveyances completed in 1951, 1952, and 1953, Certificates of Sanitary Construction were awarded for 144, or 63 percent.

Construction of Dining Cars

The typical modern dining car is about 85 feet long, seating 36 to 48 persons. Articulated twin units consist of 1 car, which seats from 64 to 68 persons, and an adjoining car, which contains the kitchen and either dormitory facilities, on an overnight run, or a lunch counter, if used in day service. Triple units have dining space in the cars at either end, with kitchen and dormitory facilities in the center car.

A multitude of limited facility cars are used either in combination with, or in lieu of, dining cars. These include coffeeshop, grill, lunch, cafe, buffet, counter, club, tap, bar, tavern, and lounge cars. Designs are usually as varied as the names, but they are not so different as their designations would suggest.

"Dining car," in Public Health Service sanitation terminology, means any railroad passenger conveyance on which food or drink is regularly prepared, stored, or served (9). Lounge and bar cars, snack cars, the recently introduced vending machine cars—and even the news butcher who peddles food and drink through coaches—all come under surveillance by Service inspectors.

Probably the most obvious condition one notes on his first entry into a dining car kitchen is that space is extremely restricted. Since the kitchen and pantry are, usually, only about 30 feet long, practically every inch of available space is utilized in their construction. Operations must be conducted efficiently, and the old maxim, "a place for everything and everything in its place," must be observed punctiliously.

Perishables must be refrigerated, utensils must be washed and treated bactericidally, and all of the other facilities required for full-scale restaurant operations must be crowded into a little more than one-third of the area of a railroad passenger car. Consider, in addition, the proximity and heat of the ranges and the lurching and swaying of the train as it travels at high speed, and you may well be amazed that meals of such quality, and in such quantity, can be prepared and served.

The "conventional" dining car is equipped with a coal range, charcoal broiler, steam table, steam coffee urn, manual dishwashing facilities, and ice refrigerators. Special studies, liberally garnished with trial-and-error experiments, demonstrated that certain structural changes would result in better cleanability and sanitation in dining car kitchens, and would at the same time improve the comfort, convenience, safety, and operating efficiency of crew members. Thus, in the "improved conventional" diner, the modifications made, usually, have been in the fuel used for cooking and the refrigeration method. Also, mechanical dishwashing and more electrical equipment are often added.

Many roads turned to pressed sawdust logs, instead of coal, for cooking fuel, because the pressed logs were more easily stored and their use resulted in a somewhat cooler and cleaner kitchen and eliminated the noxious coal gases. Other lines converted their ranges to burn oil, or butane or propane gas (10). These fuel improvements gave the employees a much cleaner and cooler kitchen and also faster and more uniform heat. There was, moreover, a saving of precious space, which is at a premium in any dining car kitchen. Certain roads by installing electric ranges further improved these factors.

Refrigeration came in for its share of modification. For many years railroads had used ice exclusively. But ice had some serious disadvantages as a refrigerant for dining car purposes. Its bulky form took up much valuable refrigerator space. More important, from the public health viewpoint, the uneven, relatively high, and uncontrollable temperatures often resulted in deterioration of foodstuffs and made possible the growth of any pathogenic bacteria which might have been present.

Dinner in the modern diner.

Some railroads have found that dry ice (carbon dioxide) refrigeration overcomes the shortcomings of ice made from water (11). Since dry ice is more compact, it conserves space needed for the storage of perishable foods. Dry ice refrigeration units may be equipped with thermostatic controls which permit, to some extent, the stocking of frozen foods. Moreover, dry ice lasts six times as long as water ice. Icing is done inside the car, thus eliminating the need for overhead ice bunkers through which dust often entered.

Several carriers have installed mechanical refrigeration. Elimination of ice storage compartments of any kind increases refrigerator capacities by as much as 30 to 40 percent. The low temperatures which can be achieved and

their high degree of uniformity enable the wide use of frozen food products.

Blueprints for an "all electric" diner were drawn in 1936, but the first such car was not actually built until 1949 (12). Two-story dining cars are now under construction. Even three-level diners are within the realm of speculation. As railroads seek new methods of improving their dining service, the future appears to point to the electronic diner which is, in fact, already in limited use (13). The most important use of electronics will be, probably, in the realm of microwave cooking, or what may be more accurately described as "food conditioning." Experimentation with this method (14), conducted by railroads in the past few years, has demonstrated that the system has

several important advantages over current methods. It will solve many of the existing sanitation problems, but it will, undoubtedly, intensify or create others.

Although dust control is a problem, to a certain degree, in practically any food establishment, the problem is much greater on dining cars. Special precautions must be taken since roadbed dust which might carry pathogenic bacteria is easily sucked into these mobile restaurants as the trains speed along. Caps must be provided over floor and refrigerator drains, or water-sealed traps must be built into drain-lines, to prevent the infiltration of dust. Windows and doors must be sealed or tightfitting. The practice of opening the kitchen loading door to increase air circulation long ago was recognized by the Service as a potential hazard.

Adequate ventilation of dining car kitchens has long been of concern to railroad officials, operating crews, passenger car builders, and the Public Health Service. Early attempts to reduce radiant heat, improve ventilation, and enhance crew comfort included the application of grills with filters to the side doors and the increased use of exhaust fans. Smoke pipes, oven doors, and the fronts of combustion chambers were insulated, and movable insulated shields were installed in front of the stoves for the protection of the cooks.

Each of these measures improved conditions to some degree, but dining car kitchens continued to be far from ideal work areas. Until recently, despite the modernization of passenger accommodations beginning around 1930, little attention had been given to the air conditioning and ventilation of kitchens and pantries. The design engineer was confronted with many developmental problems, and it was not until 1946 that the first forced-air ventilation system for a dining car kitchen was built. Numerous improvements have been made since then, but other problems remain to be solved.

At least one railroad (and there are indications that others might follow) has adopted a new type of diner with open kitchen and pantry, permitting its crew to prepare short-order meals in the air-conditioned atmosphere enjoyed by passengers. An added advantage is that, since the crew works in their constant view, the passengers become their own public health in-

spectors. This tends to influence the crew to maintain a high degree of cleanliness.

Other notable improvements in the sanitary construction of dining cars in recent years include:

- Increased use of noncorrodible, nonporous, and easily cleanable materials, such as stainless steel.

- Rounding of joints, filling and finishing of construction seams, and enclosing of inaccessible spaces, to promote cleanability and to eliminate harborage for vermin.

- Installation of adequate and convenient hand-washing facilities.

- Provision of proper facilities for washing and bactericidal treatment of utensils, whether done by manual or mechanical means.

- Improved methods of storing or disposing of garbage.

- Increased lighting on working surfaces and in lockers and refrigerators.

- Provision of suitable facilities for the storage and washing of ice for use in beverage glasses.

- Installation of wells with hot or running water for storage of frozen dessert dispensers.

- Construction of shelves, can openers, tray and knife racks, and other equipment so they can be easily removed and cleaned.

Also, increased use of dormitory cars with sleeping, ablutionary, toilet, and clothing storage facilities has encouraged personal hygiene of crew members and contributed materially to sanitation of dining cars. Some railroads bought new equipment for this purpose. Others converted old coaches, lounge cars, or other equipment into employees' quarters.

Public Health Service Inspections

The Association of American Railroad Dining Car Officers and the Association of American Railroads' Joint Committee on Railway Sanitation assisted in the preparation of a manual, the "Handbook on Sanitation of Dining Cars in Operation" (2), published in 1952, which was designed to assist those who must apply the principles of food sanitation in routine dining car operation and maintenance.

The official dining car inspection report is based on the sanitation standards given in the

published handbooks. Weights have been assigned the various items of sanitation on the form so that dining cars can be rated numerically. This affords a means of comparison, both among cars of one railroad and among the diners of different carriers. It is, also, a means of measuring and evaluating advancement in the dining car sanitation program.

More than 2,000 dining car inspections are conducted annually. Continuous improvement in sanitation of dining cars in operation is indicated by the gradual rise of the national average sanitation rating of all conveyances inspected. The average rating rose from 86.7 in 1951 to 89.0 in 1953. A Certificate of Sanitation is awarded to a carrier for each dining car which rates 95 or higher on inspection. The certificate is posted aboard the conveyance where it can be easily seen by passengers and employees, thereby stimulating interest in sanitation and promoting competition among crews. Certificates of Sanitation were issued for only 17.3 percent of the dining car inspections in 1951. The percentage increased to 24.1 in 1953. Also, in that year, the Service awarded a special citation to the first major railroad whose dining cars had all rated Certificates of Sanitation (15, 16).

The "good ol' days" custom of obtaining meals at station stops has been continued on certain runs; it is being revived or initiated on others. Sanitation of these establishments comes under local control since they cater also to the non-traveling public.

Supplying dining cars, particularly with perishables, is a serious consideration. Commissaries with adequate storage and handling facilities and competent personnel must be established along the line to restock the cars on long runs. Since these establishments, of which there are about 200, do not serve the local public, they are usually inspected only by the Service.

The use on trains of vending machines which dispense sandwiches, ice cream, cake, crackers, doughnuts, fruit, candy, coffee, milk, juices, and soft drinks has increased in the past few years. There are indications that this trend may continue. The machines, usually installed in a coach, may supplement or supplant dining car service. Preparation, storage, and handling of

foods at supply sources, replenishment of stocks aboard cars, and cleaning and servicing of machines—all are scrutinized by Service inspectors. In addition, close liaison is maintained with equipment designers and fabricators to assure, for example, that refrigeration is adequate, that the machines are easily cleanable, that food contact surfaces are of nontoxic materials, and that vermin harborages are not afforded within the units.

Much has been done to ascertain and inspect sources of prepared sandwiches sold by the

Courtesy ACF Industries, Inc.

Kitchen and pantry of a modern dining car.

news butcher. In the past, disease outbreaks which have been attributed to such foods were traced to questionable sources of supply. Personal hygiene of employees has not always been up to desirable standards. Refrigeration has often been inadequate, and storage and disposal of garbage and other refuse have frequently been unsatisfactory. To overcome these hazards, many railroads do their own vending from the dining cars, by sending crew members through the train with food and drink. In any case, concessionaires are held to the same rigid standards of food sanitation as the dining car department, and they are subject to the same strict and frequent inspections.

To assure compliance with those provisions of the interstate quarantine regulations pertaining to the serving of wholesome foods, the safety of water, the purchase of shellfish from approved dealers, and the pasteurization of milk and frozen desserts, the dining car sanitation program extends beyond the railroad's facilities to the very sources of supply. Long-established arrangements have been continued with State health departments for routine supervision of suppliers. Each year about 3,000 inspections are made of sources of water, milk, and frozen desserts.

To keep carriers informed of the status of each supplier, the Service publishes the "Official Classification of Railroad Watering Points" and the "Official Classification of Milk and Frozen Dessert Sources." These are semi-annual listings of sources of supply which have been inspected and classified as approved, provisionally approved, or prohibited for the use of interstate carriers. Provisionally approved sources must effect the necessary corrective action without delay or they risk being classified as prohibited sources. Lists of shellfish dealers who hold unexpired and unrevoked certificates issued by State authorities also are published regularly by the Service.

Disease Outbreaks

If a disease outbreak occurs on a train, or is suspected of resulting from food or drink consumed or environmental conditions encountered on a conveyance, the Public Health Service and State and local health departments have technicians who cooperate in epidemiological surveys to determine the cause of the outbreak and to prevent recurrence. Fortunately—no doubt as a result of the far-reaching preventive measures—railroads find it necessary to avail themselves of this service very infrequently.

Data on disease outbreaks resulting from food or drink consumed on dining cars are indeed meager. This is easily understandable. It is well known to public health workers that complete and accurate reporting of all disease outbreaks is virtually impossible. This is particularly true of most food-poisoning illnesses which, though often violent, are of comparatively short duration. Many victims do not seek

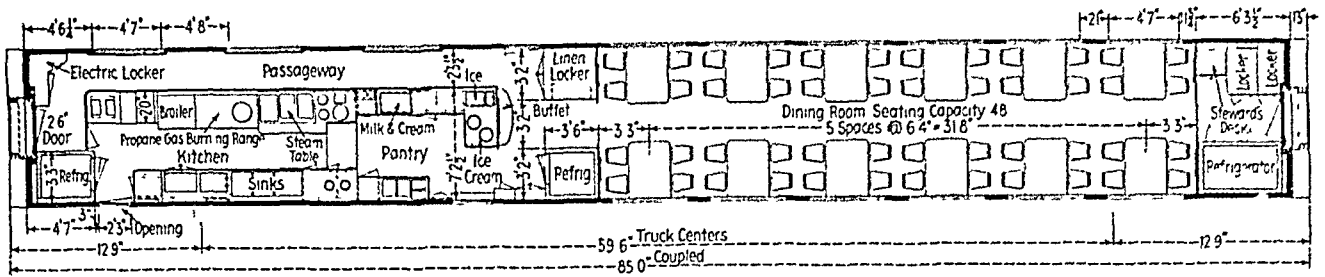

medical assistance, and recovery is usually rapid and complete. Because railroad passengers scatter to various parts of the country upon completion of their journeys, epidemiological investigations are complicated. Generally, cases are reported to public health officials only when the outbreak occurs en route, when many affected passengers debark at a common terminal, or when groups of afflicted passengers travel together in special parties.

During the 1942-45 wartime period, 10 disease outbreaks involving 668 persons, of whom 434 were military personnel, were traced to food or drink consumed on railroad trains. In the next 8 years (1946-53), as the dining car sanitation program gained momentum, 5 outbreaks with 75 cases were reported. Two of these, totaling 40 cases, occurred during one extensive special movement in which railroads were taxed to the limit, requiring the use of much standby equipment and the employment of many extra personnel. Notwithstanding the acknowledged shortcomings of morbidity reporting peculiar to outbreaks among railway passengers, available statistics appear to substantiate the effectiveness of the Service's dining car program.

Training for Employees

Through routine inspections of dining cars in operation, the Public Health Service found that structural improvements alone would not raise sanitation to the desirable level. To reduce the possibility of foodborne illness, employees needed to have a thorough understanding of the principles and reasons for food service sanitation, proper use of equipment, and approved methods of conducting operations. Railroad officials agreed with this conclusion, and intensive training programs became the order of the day, beginning in the 1940's.

Some of these training courses are conducted by the carriers themselves. Some are conducted exclusively by the Public Health Service. But, generally, dining car departments and the Service collaborate closely. Sometimes a dining car is turned into a classroom, and courses are held in commissaries, union halls, or other available meeting rooms. Teaching methods vary, but the emphasis is on informal discussions.

Courtesy of Car Builders' Cyclopedic.

Floor plan of a typical dining car.

Occasionally, carriers make attendance mandatory at training courses; but, for most, it is voluntary. In either case, there usually is little discernible difference in the turnout or level of interest. Crew members seem glad to have the opportunity to discuss their problems and to learn approved methods and standards of food sanitation. Many, of their own volition, attend subsequent training sessions. The Public Health Service issues a wallet-sized Certificate of Attendance to each employee completing the course.

Some carriers have requested refresher courses at 6-month intervals. Dining car employees' organizations have become enthusiastic about the promotion and expansion of such refresher training. Significant improvement in operation of diners has been noted on many carriers, and there have been definite indications that the training sessions have impressed the crews with the importance of the principles of sanitation and hygiene.

One dining car superintendent, whose company in 1 year spent \$8,000 on training courses, remarked, "The improvement in operations accruing from food service employees' training programs is in itself sufficiently substantial a return for the investment made."

Most railroads, in an effort to improve and maintain sanitary conditions on their diners, engage traveling inspectors or inspection teams who board cars in service, observe operations, call attention to defects in equipment and methods, and give instruction in proper food service. A recent innovation has been the training by the Service, of inspectors of certain companies to follow the official Public Health Service inspection procedure. Ratings obtained by these inspectors are not considered official for the purpose of issuing Certificates of Sanitation,

or for computing the annual average rating of their cars. However, this system has proved to be a valuable adjunct to the Service program and has significantly raised the level of sanitation on diners.

Education of employees is a never ending phase of the dining car sanitation program. Personnel of the Service's regional offices give instruction in food service sanitation, interpret regulations for carriers as an aid in the formulation of company rules governing dining car employees, and assist carriers in developing visual aids and other education materials.

In 1953, the Public Health Service produced its first film devoted specifically to the subject of dining car sanitation. This visual aid, actually a filmstrip, is entitled "Food Sanitation in Dining Cars." It was produced with the cooperation of the Association of American Railroad Dining Car Officers and is available to carrier companies or employee organizations.

Many carriers now have company publications devoted exclusively or in part to dining car service. These usually include items on particular phases of sanitation, to serve as constant reminders to crew members that sanitation is a never ending and exceedingly important part of their service.

The advancement in dining car sanitation is all the more remarkable when one considers that no railroad has ever, with the exception of the war years, realized a profit from the operation of dining cars (5). Still, development and improvement of dining service are proceeding persistently, and railroads are justifiably proud of their equipment, food, and service.

While the Public Health Service program of dining car sanitation has its legal basis in the Interstate Quarantine Regulations, it has been conducted, historically, on a cooperative and

educational basis with the carriers. The Service is primarily interested, not in arbitrary exercise of its powers, but in a high level of sanitation on dining cars. Because virtually all carriers are intent on the same objective, the program has traditionally had their wholehearted support.

Results of the Cancer Teaching Program In Dental Schools

By RAYMOND F. KAISER, M.D.

A PROGRAM of grants to dental schools for the integration and improvement of cancer teaching was inaugurated in 1948 as a step toward the control of intraoral neoplastic disease through earlier diagnosis and treatment. The program has been expanded steadily until, at the present time, the National Cancer Institute is administering Public Health Service grants to 43 dental schools throughout the country. The results have been gratifying, especially in that the new generations of practicing dentists are aware of the important part they can play in the early detection of cancer in their patients.

It was the opinion of the staff and advisers of the National Cancer Institute in 1947 that the dental profession could take an important part in cancer control. This feeling was based on a number of factors. Among them was the knowledge that the most effective way to discover cancer in an early stage is through careful periodic examinations. Because the dental profession, through its public education program, has been successful in motivating people to visit their dentists regularly, the dentist has an unequalled opportunity for periodic inspection of the oral cavity among his patients under the most desirable conditions. Therefore,

the dentist, if properly informed and trained, is in a position to discover many early cases of cancer.

In addition, experience has shown that an appreciably large number of patients with intraoral cancer, particularly cancer of the gingivae, consult their dentist prior to seeking advice from their physician, thereby providing the dentist with the initial opportunity to discover and observe early cancer. Coupled with this is another advantage possessed by a member of the dental profession. That is the opportunity to follow up the patient whom he has advised to seek further medical attention. This followup can be accomplished by the simple procedure of scheduling a dental appointment subsequent to the date the patient was referred for medical attention.

Often the dentist can aid cancer control by searching for and correcting oral conditions which may contribute to the causation of cancer. Finally, the dentist can contribute to the welfare of the cancer patient through proper dental care and preparation of necessary appliances and prostheses.

In 1947, at a joint meeting of the National Cancer Institute and the Council on Dental Education of the American Dental Association, it was agreed that the dental profession in general would be aided if a program were initiated to orient the profession to the specific dental aspects of the cancer problem. It was agreed that this orientation could best be accomplished by an approach to the oncoming generation of dentists through integration and improvement of

Dr. Kaiser is chief of the Field Investigations and Demonstrations Branch of the National Cancer Institute, National Institutes of Health, Public Health Service.

oral cancer instruction in the dental schools. With the approval of the National Advisory Cancer Council, the institute undertook a program of grants under which approved dental schools were eligible to receive up to \$5,000 annually.

The history of participation of the 43 schools cooperating in the program has been as follows:

<i>Schools</i>	<i>Year of participation</i>
17-----	7th
16-----	6th
4-----	5th
2-----	4th
2-----	2d
1-----	1st

NOTE: 1 school participated for 2 years but was unable to continue because of personnel problems.

Upon the initiation of the program in each school, a member of the faculty was designated to serve as cancer coordinator. At present the coordinators are distributed in the following disciplines:

Oral pathology-----	11	Histology-----	1
Oral surgery-----	6	Associate dean-----	1
General pathology---	7	Associate professor of	
Oral medicine-----	4	dentistry-----	1
Deans-----	4	Oral diagnostician---	1
Dental medicine---	2	Dental prosthesis---	1
Clinical pathology--	1	Periodontology-----	1

This current distribution reflects a turnover of approximately 25 percent of the coordinators since the inception of the cancer teaching program, although, by and large, the group has remained relatively stable. In the majority of the schools, the coordinator has the benefit of the advice and assistance of a cancer teaching committee, appointed during the initial period of the grants program.

Areas of Deficiency

At the outset of the program these individuals and committees reviewed the teaching of cancer within their own schools and, with the exception of a very few schools, uncovered the following findings in relation to such instruction:

A general belief prevailed within and outside the schools that dentistry was essentially a restorative art and that knowledge of cancer was not pertinent to dental practice.

The teaching of oral cancer was unorganized, uncoordinated, nonsystematic, and casual.

There was not time in the dental curriculum for courses other than those concerned with restorative dentistry.

A scarcity of suitable teaching material existed among patients admitted primarily for dental treatment.

Little or no histopathological cancer material was available.

Practically no student slide collections of cancer were available.

Very little opportunity existed for students to observe cases of clinical cancer either on a demonstration basis or through clinic or hospital experience.

Teaching materials and equipment were inadequate to provide instruction on the cancer problem.

Experienced personnel qualified to provide cancer instruction were insufficient.

There was generally inadequate correlation between preclinical and clinical teaching.

These represent, in general, the major areas of deficiency encountered by representatives of the schools, although others of varying degree and type existed in some schools.

Allocation of Funds

It was recognized on initiating the cancer teaching program that the most effective methods of improving cancer instruction would vary from school to school, and it was decided that each school should have the opportunity to develop the type of program which best met its particular circumstances.

An analysis of the funds requested by the dental schools gives some indication of the uses to which the schools put the grants. In the first year of operation the total grants for all participating schools were distributed in this manner: 57 percent for personnel, 19.1 percent for permanent equipment, 13 percent for consumable supplies, 5.9 percent for travel, 2.4 percent for other expense, and 2.6 percent for overhead. In 1954 the funds requested were distributed in the following manner: 75.7 percent for personnel, 8.0 percent for permanent equipment, 5.9 percent for consumable supplies, 4.5 percent for travel, 0.4 percent for other ex-

pense, and 5.5 percent for overhead. During the course of the program there has been a general tendency to increase the percentage for personnel and overhead and to decrease the percentage in the other categories—consumable supplies, permanent equipment, travel, and other expense.

More Time and Materials

The schools have shown many similarities in their efforts to improve cancer teaching. All of the schools in one way or another have been able to rearrange their curriculums to add a sizable number of clock hours of cancer instruction in both didactic lectures and laboratory exercises. Additional emphasis has been placed on cancer in oral pathology by 36 schools, general pathology by 27, oral diagnosis by 24, oral surgery by 23, oral medicine by 4, dental medicine by 2, prosthetics by 1, and periodontia by 1. In addition, new courses of various types specifically concerned with oral cancer have been added to the curriculum by 25 schools.

Since effective teaching in oral cancer, as in any type of cancer instruction, is directly related to the quantity and quality of clinical material available for presentation, 24 schools have supplemented their clinical teaching by arranging for their students to participate in tumor clinic activities through association or affiliation with teaching hospitals. Two additional schools have organized their own clinics or oral diagnostic centers; 11 additional schools present patients to students through demonstration clinics; and 2 schools accomplish this by means of ward walks. Sixteen schools conduct tumor conferences as a part of their teaching programs. Thus, an increasing number of dental students have an opportunity to observe patients with cancer in all stages of the disease and to become familiar with differential diagnosis along with the various methods of therapy.

To increase histopathology material for student instruction, 26 schools have established a biopsy diagnostic service for dental practitioners. In most instances this tissue service was established by the expansion of existing facilities through the purchase of equipment and the acquisition of technicians under the grants,

but in 9 schools grant funds were used to initiate and establish new tissue laboratories. In all 26 schools student work with tissue slides has been markedly increased, and for the first time adequate individual student slide collections have been made available. Four schools require students to attend autopsy examinations of cancer patients. In the schools providing this biopsy service there has been a marked, steady increase in the number of biopsy specimens received. Without exception the schools consider this increase one measure of the success of their cancer teaching program since recent graduates are contributing the greater share of the biopsy specimens. Twenty-four schools demonstrate how to take a biopsy, while in 16 schools the student is required to take one or more biopsies and follow through the processing of the specimen to the histological slide.

The grant program has made it possible for all participating dental schools to strengthen their visual education and teaching materials. These vary from school to school but include color photographs of cancer lesions, lantern slides, histopathological slides, photomicrographs, exhibits, specimen displays, mouldages, models, films, and filmstrips as well as equipment such as cameras, projectors, screens, slide viewers, microscopes, and scopicons. Four schools have prepared short films on biopsy techniques for the instruction of students as well as practitioners.

Enlarged Staffs

Further evidence that the schools' interest in cancer teaching has increased in spite of the limited amount of the grants is the fact that 13 professional persons and 21 nonprofessional laboratory technicians, photographers, and a laboratory secretary have been added to the staffs of the schools as a direct result of these grants. In addition, numerous staff members have contributed time and effort toward the teaching program without any monetary recompense from the grants. In the field of personnel, two schools have used some of their funds for teacher training.

The grants have stimulated nine schools to undertake cancer and other research activities, and they have established programs which pro-

vide students the opportunities for investigative work.

Special lectures and seminars have been used by 24 schools as a method to increase cancer instruction. As in many teaching programs, and this one is no exception, the cancer teaching spills over from the undergraduate area into the postgraduate. Students, as well as practitioners, participate in the lectures and seminars mentioned above. Ten schools have established specific programs of postgraduate education. One of these has initiated a case history service for practitioners, and the remainder offer refresher courses and special or postgraduate courses for practitioners and graduate students.

This summation of specific accomplishments as a result of the stimulation of cancer teaching grants is based on special reports from the individual schools expressing objectively the actual results attributable to the grants and a personal knowledge of the programs in a number of the schools gained through field visits by the staff of the National Cancer Institute. Many of the coordinators have expressed the belief that a cancer learning test developed for dental schools is valuable for measuring the improvement of cancer teaching within their institutions. Twelve schools have reported a steady improvement in the scores of their students during the years they have participated in the testing program.

Summary

A number of years have gone by since the initiation of the cancer teaching program, and

it is now possible to take a long-range view of its effect and to enumerate a number of general accomplishments:

- It has made possible the expansion of oral cancer instruction and increased the curriculum time devoted to cancer teaching.

- It has increased clinical material for dental students.

- It has increased student participation in clinical cancer activities.

- It has promoted the development and utilization of teaching materials, facilities, and equipment.

- It has helped correct the traditional view that knowledge of cancer was not pertinent to dentistry and helped to clarify the role of the dentist in control of the disease.

- It has strengthened cooperative relationships between the medical and dental professions.

- It has increased the dental students' awareness of cancer and has impressed on him his responsibility for the early recognition of cancer.

- It has developed teaching personnel within dental staffs.

- It has augmented and enhanced the quality of oral cancer instruction.

- It has increased cancer facilities and services.

- It has stimulated the establishment of diagnostic biopsy services.

- It has stimulated and expanded research interests of dental school facilities.

- It has pointed up the need for cancer instruction in postgraduate fields.

- Lastly, it has accomplished a general improvement in the teaching of oral cancer.

In a New York State Health Department study, a comparison of original death certificates and certificates prepared from autopsy protocols revealed an appreciable degree of inaccuracy in cause-of-death statements.

Accuracy of Cause-of-Death Statements On Death Certificates

By GEORGE JAMES, M.D., M.P.H., ROBERT E. PATTON, M.P.H.,
and A. SANDRA HESLIN, M.S.

THE BASIC DATA on which public health activities have been planned have come primarily from vital statistics. Birth and death certificates have provided information essential to the operation of nearly all health programs. Since the start of the vital registration systems in this country, the emphasis has been on completeness of reporting. The entrance of a State into the birth or death registration area was determined primarily by its achieving a stated percentage of completeness of reporting, and no other criterion for accuracy in vital statistics has yet been generally employed.

Dr. James, with the New York State Department of Health continuously since 1949, is now assistant commissioner for program development and evaluation. He is also associate professor of preventive medicine and public health, Albany Medical College. Mr. Patton, formerly associate statistician, bureau of statistics, New York State Department of Health, is now assistant director of the New York State Department of Mental Hygiene. Miss Heslin is a biostatistician with the State department of health.

Questions have been raised, however, as to the accuracy of the information on these certificates, and some attempts have been made to assess the accuracy of various items. Swartout and Webster (1) reviewed earlier studies of the accuracy of cause-of-death statements and compared autopsy diagnoses for 8,080 persons in Los Angeles Hospital with the cause of death which they believed would have been listed had no autopsy been performed. They found 79 percent agreement between the diagnoses, with the percentage by categories varying from 100 percent for measles, scarlet fever, and cancer of the mouth to 16 percent for softening of the brain. When they used broader categories for their comparisons, the agreement reached 90 percent. Agreement was only 50 percent for those patients who were admitted to the hospital within 48 hours of death. All diagnoses were made by the authors themselves, using the fifth revision of the International List of Causes of Death, and multiple causes were resolved through the Manual of Joint Causes. They did not study the actual certificates filed by the attending physician.

In 1949, Dr. A. G. Evans, in an unpublished study, analyzed a sample of 3,900 from a total

of 161,600 death certificates for the years 1946 and 1947. Based upon his own judgment as to what constituted a satisfactory statement of the cause of death and without any consideration of autopsy data, he discovered that 57 percent were defective. Of this defective group, almost half had incomplete medical certification, 24 percent used obsolete or unacceptable terms, and 28 percent represented inaccurate medical certification. He suggested greater emphasis on querying of death certificates by health officers. On the average, only about 3 percent of death certificates in the Nation as a whole are queried, and, according to a recent survey, only 8 State and Territorial health departments estimate that they are querying more than 5 percent of death certificates submitted (2).

Pohlen and Emerson (3) obtained cause-of-death data based on both ante-mortem and post-mortem findings from 15 cooperating hospitals in New Jersey and New York State. Deaths from cancer were analyzed in an attempt to determine the accuracy of the diagnosis and of the determination of the anatomical site of the cancer when based on clinical data alone. Of 3,462 deaths found at autopsy to have been due to cancer of various sites, the diagnosis for 77 percent was etiologically correct; for 77 percent it was topologically correct; and for 67 percent it was correct in both ways. Cancers of certain sites, such as the breast, the pharynx, and the rectum, were correctly diagnosed ante mortem relatively more often than were those of sites such as the brain, the liver, and the bile ducts. In addition, the autopsy data revealed that 148 deaths attributed to cancer on the clinical diagnosis were actually due to some other cause.

Korns and Lintz (4) concluded from a review of 500 autopsy protocols from 5 hospitals that there was an 11 to 20 percent disagreement between the medical statements appearing on death certificates and the pathological findings at autopsy. They used the fifth revision of the International List of Causes of Death and the Manual of Joint Causes.

The present study was made to determine how closely the reporting of the cause of death under the current system tallies with the best possible estimation of the facts. The initial

problem was to determine what could be used as a standard for comparison; in other words what was the "true" underlying cause of death? In general, a diagnosis made on the basis of a complete, competently performed autopsy and a good clinical history is as close to the truth as modern medical science can come. This procedure, of course, does not completely solve the problem, because the pathologist does not and cannot always state the underlying cause of death singly and unequivocally. Multiple factors may be present, any one of which could cause death or whose effect may lie only in their particular combination. The present vital statistics system, however, is geared in such a way that each death must be attributed to one and only one cause. Needed to measure the accuracy of this system, therefore, is a theoretically true underlying cause of death, defined as that cause of death which a well-trained physician would enter on the death certificate after he had obtained all possible information, including a clinical history and findings of a complete autopsy. In this study, such a theoretically true cause of death was determined for a large number of deaths occurring in upstate New York and compared with the cause entered on the original death certificate. Data obtained were then used to evaluate the accuracy of the cause-of-death statements on the original certificates.

Study Method

The records of all autopsied deaths occurring in 12 hospitals in the Albany, N. Y., region in 1951 and 1952 were examined by a team of three third-year medical students working under the junior public health intern program of the New York State Department of Health. These students had received special training in how to complete a medical certification section of a death certificate, and their abilities in this regard were tested carefully by the authors. Each autopsy protocol, including the clinical summary, was reviewed, and if the autopsy was complete, a standard death certificate was filled out, the pathologist's results being used in completing the cause-of-death statement. A total of 1,889 such certificates were completed and analyzed. All of the pathology services in

the cooperating hospitals were under the direction of a physician qualified under New York State's public health law, which requires qualifications equal to those required by the American Board of Pathology.

These certificates, called autopsy certificates in this report, were then coded by the regular coding staff of the New York State Department of Health according to the sixth revision of the International Lists of Diseases and Causes of Death in the same manner as are all death certificates. The regularly filed death certificate, called original certificate, was then examined for each of these cases, and the originally coded cause of death was entered on the completed autopsy certificate. The data were grouped according to 30 broad categories of cause of death similar to those used by the New York State Department of Health in its published vital statistics reports.

In developing the method used in this study, two questions had to be answered by small methodological studies:

1. Could the three reviewers, working independently, draw the same conclusions as to the underlying cause of death from identical autopsy data?

To answer this question, each of the three reviewers prepared autopsy death certificates from a series of 50 consecutive autopsy protocols from the files of a teaching hospital. For 46 of the 50 cases (92 percent), there was complete agreement within New York State's vital statistics groupings; for 2 cases (4 percent) 2 of the three reviewers were in agreement; for the remaining 2 (4 percent) each reviewer listed a different cause of death. Of the 46 autopsy certificates on which all 3 agreed, there was disagreement with the original certificate on 6 (13 percent). When each reviewer was tested

Table 1. Number of deaths by cause according to original death certificate and autopsy certificate

separately against the 50 original certificates, the disagreements were 8, 8, and 9, or 16, 16, and 18 percent. Hence, not only did the reviewers agree well among themselves, but each disagreed about equally with the original. Although this test did not provide conclusive evidence that there was no reviewer bias, it was decided to permit each reviewer to work independently on different sets of autopsy protocols and to combine their results for the final analysis.

2. If there should be marked differences between the autopsy and original certificates, how would it be known that it was partly due to the additional data uncovered at autopsy instead of wholly to avoidable errors by the physician who completed the death certificate?

To answer this question, the reviewers, working as a team, studied the ante-mortem clinical

records for 98 consecutive autopsied deaths, agreed upon a medical certification of death for each, and prepared new death certificates without reference to autopsy data. Then they studied the autopsy protocols and prepared another set of certificates based upon all available information. If the certificates prepared from the clinical records did not compare much more favorably with the autopsy certificates than did the original ones, the errors in cause-of-death statements on the originals could not be attributed wholly to avoidable errors by the physician who completed the death certificate.

When the three sets of certificates were compared, it was found that the original and autopsy certificates for 20 (20 percent) of the 98 deaths studied disagreed, but that in only 4 of these did the certificate prepared from the clinical records agree with the autopsy certificate.

Hence, if the physician had completed the certificate properly on the basis of the ante-mortem evidence, agreement between the original and autopsy certificates would have been only 4 per cent greater. It was concluded that in this sample, taken from a large teaching hospital where physician practices on death certification were good, there was an appreciable amount of new information supplied by autopsy which could refine the cause-of-death statistics.

This study made no attempt to assess the physician error in recording the ante-mortem data for the total group of 1,889 cases separately from the error due to inadequate information. The methodological study mentioned above was taken as an indication that a sizable portion of the difference between the autopsy and the

original certificates was due to additional data found at post mortem.

Cause-of-Death Comparisons

Table 1 shows the deaths tabulated by cause groups, both by the original coding and the coding of the autopsy certificates. As can be seen, inaccuracies in the original cause-of-death statement led to an overstatement or understatement of the importance of several major causes of death. For instance, the use of autopsy data changed the number of deaths from tuberculosis (001-019) from 48 to 56. Since the deaths studied were not a representative sample of deaths in the State, this finding cannot be considered as proof that the death rate from tu-

berculosis as given by the reports of the New York State Department of Health is too low. It merely suggests that there may be some underreporting of deaths due to tuberculosis.

Although the number of deaths from syphilis and its sequelae (020-029) was numerically small, there was a significantly large difference in the number of deaths from this cause when the autopsy data were used. Furthermore, an investigation of the incorrectly allocated certificates showed that the difference could be attributed to deaths from "aneurysm of the aorta." Of the 8 deaths ascribed to this cause on the original certificate, 7 of them were found at autopsy to be nonsyphilitic. Three of these certificates had been queried to discover whether or not the aneurysm was syphilitic, but the physician certifying the death in each case had not replied to the query. If this practice of listing "aneurysm of the aorta" as the cause of death occurs throughout the State, many of the deaths attributed to syphilis are wrongly allocated.

The cardiovascular renal group as a whole (330-334, 400-468, and 592-594) showed little change, although there were many differences within the group. The number of deaths attributed to general arteriosclerosis (450) showed a significantly large increase when autopsy data were used. The hypertensive heart disease group (440-443), in particular, showed a significantly large decrease. The lack of

clinical information or the lesser attention given to this group of diseases by pathologists may be a partial explanation for these differences, as well as for the significantly large decrease in the proportion of deaths attributed to diabetes mellitus (260). In certifying these deaths, the physician may have given more weight to clinical information than did the pathologist.

Certain categories, such as malignant neoplasms and accidents, were relatively unchanged by the use of autopsy data. The cause of death in these categories seemed to be relatively well reported.

Although the similarity, rather than the difference, in the overall distribution of the two groups of records by cause of death is perhaps the striking factor in table 1, it can be seen from table 2, which shows the distribution of the deaths by the cause given on the original certificate and by the cause given on the autopsy certificate, that the similarity is due in part to compensating errors. Actually, there was complete agreement between the originally coded four-digit cause of death and the four-digit cause coded on the autopsy certificate for only 865, or 45.8 percent, of the deaths. There was agreement for 52.2 percent of the deaths in terms of three-digit codes as used in the International List and for 71.0 percent in terms of the 30 broad cause groups shown in table 2. Thus, slightly more than one-fourth of the deaths were certified in such a way as to be

classified in a different major group, but compensating errors did decrease these differences, as shown in table 1.

The deaths allocated to pneumonia are a good example of the compensating effect of the differences in allocating causes of death on the two groups of certificates. According to the original certificate, there were 57 deaths from pneumonia among the 1,889 studied. There were also 57 deaths attributed to pneumonia on the autopsy certificates, but only 25 of these 57 were the same ones. In other words, less than one-half of the deaths attributed to pneumonia were actually due to pneumonia according to the autopsy report, but other errors completely compensated for this error.

Characteristics of Study Group

As previously mentioned, the deaths included in this study are not a representative sample of all deaths in upstate New York, nor are the hospitals in which they occurred a representative sample of all hospitals.

Table 3 shows the differences in the age and sex composition of the study group and of all deaths in upstate New York in 1951. There is a lower proportion of deaths in the study group at ages 65 years and over for males and at ages 55 years and over for females. Table 4 shows some marked differences in the distribution of deaths by cause for the study group and for all deaths. These differences undoubtedly occurred, because deaths from certain causes are selectively autopsied. The great underrepresentation of deaths due to heart disease in the study group indicates that the conclusion regarding the inaccuracy of reporting of death due to this cause is conservative. One might expect that the differences between the stated and "true" cause of death among nonhospital heart disease deaths would be greater than among the study group since physicians attending persons dying at home from heart disease may have seen their patients only in the terminal stages and may not have had access to the diagnostic facilities of a modern hospital.

Tables 5 and 6 show the proportion of the deaths in upstate New York in 1952 that occurred in a hospital and the proportion that came to autopsy. The percentage of the deaths

from such conditions as cancer, tuberculosis, acute nephritis, and diseases of the digestive system occurring in hospitals is much higher than the percentage of deaths from such a cause as heart disease. Of all causes of death, cancer, tuberculosis, pneumonia, diseases of the digestive system, accidents, and some of the diseases of infancy stand out as those selectively brought to autopsy. On the other hand, several extremely significant causes of death, such as arteriosclerotic heart disease, diabetes, and vascular lesions affecting the central nervous system, are decidedly underrepresented among the autopsied deaths. This latter group of disorders is frequently difficult to diagnose and is often found in association with many other degenerative processes. That the cause-of-death data in the degenerative diseases lack a firm basis is further substantiated by the data in tables 7 and 8. At the older ages when these diseases are particularly prevalent, the proportion of all deaths autopsied is especially low.

Discussion

Inaccuracies in cause-of-death data may occur because:

1. The physician does not list the available material correctly on the death certificate.
2. The clinical and laboratory data available before an autopsy is performed are not sufficient to enable the physician to determine the cause of death correctly.
3. In some cases where all information, including the autopsy data, is available, it is still difficult to decide on one underlying cause of death.

The present study did not seek to assess numerically the factor of the physician's ability to record information correctly on the original certificate, although this factor was considered in the analysis of the cause of death among the 98 consecutive autopsies performed in a medical school teaching hospital with excellent attending physicians, house staff, consultants, and laboratory facilities. Using ante-mortem data of unusually high quality, the resulting diagnosis of cause of death on the so-called clinical certificate was quite similar to

¹ Numbers in parentheses are category numbers of the sixth revision of the International Lists of Diseases and Causes of Death.

that made by the physician on the original certificate. Nevertheless, there existed a large difference between either the clinical or original and the autopsy certificate. This study emphasized the source of inaccuracy listed as number 2, that is, the lack of sufficient information to determine the "true" cause of death.

It is not possible to compare the results of this study directly with those of the studies by Swartout and Webster or by Korn and Lintz. In both of those studies, cause data were categorized according to the fifth revision of the International List and the Manual for Joint Causes, whereas in this study the underlying cause specified according to the sixth revision of the International List by the person completing the death certificate was accepted by the vital statistics coding unit. Nevertheless, the results are generally similar in that they dem-

onstrate an appreciable degree of inaccuracy in general cause-of-death data.

Epidemiological studies based upon mortality data gleaned from death certificates present elaborate analyses, by age, sex, and other factors, while accepting with little question the accuracy of the basic record itself. Concern over accuracy of the specific measurement of cause of death should precede the question of the association of these causes with certain characteristics of the general population.

The present study points out a paradox: Although a large number of death certificates give an inaccurate cause of death, this error does not necessarily exert a great influence on the overall cause-of-death statistics. Approximately the same number of deaths from cancer, for example, are reported to be due to heart disease as there are heart disease deaths which are at-

tributed to cancer. This observation, however, is made for autopsied deaths among hospitalized patients, and the same compensating effect of the errors may not be found for other deaths. Within certain cause-of-death classifications, the assignment by the physician of the underlying cause of death seems to behave like a statistically random process. Even if this group of deaths were a representative sample of all

deaths in New York State, the autopsy results would change the cause-specific death rates significantly in only a few of the categories; namely, syphilis, diabetes, hypertension with heart disease, generalized arteriosclerosis, and hypertension.

Although such a compensating mechanism may give us more confidence in the overall mortality statistics, it raises serious doubts about

the use of present death-certificate data for research purposes, particularly in the field of chronic degenerative diseases. Epidemiological studies of deaths from heart disease, for example, based on such artifacts must be reexamined to determine whether there are significant biases in the way the errors are associated with the factors under investigation. Material to be used for such studies must first be refined, es-

pecially since the deaths from heart disease are so underrepresented among autopsied deaths.

Suggestions for Improvement

This study, as well as others cited, indicates a need for the consideration of procedures that will improve the accuracy and, consequently,

the usefulness of cause-of-death data. Presented here are a few suggestions that, it is hoped, local health departments may wish to develop further through demonstration projects. The suggestions apply particularly to collection of data which are to be used for epidemiological studies of the degenerative diseases. Emphasized are steps that might be taken to prevent some of the inaccuracies resulting from the absence of post-mortem data at the time the death certificate is filled out, but attention is also given to the improvement of accuracy through correct recording of available data and to the problem of multiple causes of death.

Obtaining Post-Mortem Data

One possible method of correcting inaccurate cause-of-death statements would be for the pathologist to send a copy of each autopsy summary to the local health department. This practice might be of help in resolving many of the questions posed by the present medical certifications, and it should reduce the number of certificates requiring queries to the attending physician. Many deaths, of course, do not go to autopsy, but the provision of an autopsy summary for those that do should increase the body of trustworthy data.

Another possible approach would be the re-vamping of procedures for correcting medical

certifications of the cause of death after the certificate has been filed. Some States, with legal considerations in mind, have made it difficult to make changes in the cause-of-death statement, often requiring the physician to submit special legal forms. As a first step, arrangements might be made for public health administrators to obtain changes, even if the "legal" certification of death remains the same. Physicians and hospital record rooms could be encouraged to submit supplemental unofficial data on deceased patients when such information effects a significant change in the cause of death already recorded. At least one registration area (New York City) is now employing a certificate form in which the medical portion of the record is filed separately from the "legal" portion.

Some improvement in accuracy of medical certification of cause of death can probably be made by increased efforts to educate physicians to evaluate the various pathological factors properly and to communicate their decisions accurately by means of uniform disease terms, as well as to complete the certificate accurately. Local health agencies should renew their interest in these problems. By maintaining alert, medically oriented querying programs, they can insure that physicians correct and adjust the causes of death. The daily sheaf of death certificates passing through the local health

unit should be examined by a person with medical training, one who can select those requiring followup. In addition, arrangements might be made for the health agency to receive routine reports or periodic samplings of post-mortem examinations as a guide in taking steps to correct inaccurate cause-of-death data in those records forming a basis for the agency's programs.

The Problem of Multiple Causes

The present study suggests also the need for changes in the methods of collecting and analyzing mortality data if such data are to be used for epidemiological studies of chronic disease. Even among the patients dying from these chronic diseases who are autopsied, the problem of sorting out a single underlying cause is not simple. In many of these cases, several degenerative processes have been at work, and it is sometimes difficult to attribute death to a single underlying cause. With the present aging of the population and the decrease of communicable disease fatalities, the problem of multiple degenerative processes is increasing proportionately so as to overshadow all of the excellent steps taken so far to improve cause-of-death reporting. This situation is responsible for the third type of inaccuracy in cause-of-death data mentioned above.

If present trends continue, an ever-increasing number of deaths will be attributable to any of several combinations of diabetes, hypertension, pulmonary fibrosis, atherosclerosis, heart disease, obesity, cirrhosis, senility, nephritis, and cerebral hemorrhage. The exact one of these recorded as the primary cause will often be largely a matter of the physicians' opinions of the sequence of the processes. Even pathologists observing end results with all available clinical data at hand can hardly be expected to be consistent and infallible in arranging disease patterns so as to select the underlying cause. Moreover, even if the "true" cause of death were, for example, cerebral hemorrhage, perhaps the only public health control measure available to postpone its occurrence would be an attack against an accompanying hypertension, diabetes, obesity, or nephritis. Public health recognizes that chronic diseases seem more often due to diffuse multiple causes than

to specific ones. The weakest link in the chain of disease, the best potential point for attack, may reside in an attribute rarely or inadequately counted among the pathological conditions associated with fatal illness. Moreover, the present reporting system prevents us from being able to study the total prevalence of certain serious conditions at time of death. An awareness of these facts may be partly the reason for the current emphasis on morbidity instead of mortality surveys in a search for epidemiological factors in chronic disease.

For these reasons, physicians and pathologists might record not only the underlying cause of death on the death certificate, but whatever data are available on the type and duration of each 'pathological' or pathophysiological condition present. A real challenge awaits specific local health units who wish to explore this possibility on a pilot basis. Preliminary studies based upon multiple cause analysis of routinely submitted certificates are interesting. Sagen and Vinyard (5) report that in all diseases except tuberculosis, malignant neoplasms, other diseases of the heart, and accidents, at least 50 percent of the death certificates they reviewed indicate a multiple cause. The diabetes group had the largest proportion, 87 percent, with multiple causes. Such data, however, are not as meaningful as they would be had the reporting physician been instructed to list all pathology which was present, since under current practice it is common to omit listing some conditions in completing a death certificate. The available space for the medical certification is too limited to permit the inclusion of all the many pathological processes which may be involved, a fact which suggests that the certificate might be redesigned or supplemented for special studies in selected areas. Thought might be given to including on the reverse of such death certificates a checklist of the medical conditions which are important to modern public health practice.

Summary

1. Autopsy protocols for 1,889 consecutive deaths occurring during 1951 and 1952 in 12 hospitals in the area of Albany, N. Y., were reviewed, and new death certificates were prepared from the autopsy information. These

certificates were coded and compared with the original certificates on file in the New York State Department of Health.

2. When causes of death given on the original certificates were matched with the "true" cause as determined at autopsy, the errors in the original certificates were often found to be compensating. Despite such a compensating effect, the extent of the error in a large number of specific cases raises serious doubts as to the validity of the use of cause-of-death data as a basis for epidemiological studies of degenerative diseases.

3. Certain of the degenerative diseases which figure importantly as causes of death, such as arteriosclerotic heart disease, diabetes, and vascular diseases of the central nervous system, are decidedly underrepresented among the deaths autopsied. For these causes, the percentage agreement between the original death certificate and the autopsy certificate was 72.8, 30.6, and 59.5, respectively. The fact that a large number of such deaths do not occur in hospitals suggests that even greater errors exist in the present mortality data for these conditions.

4. Suggestions made for improving the accuracy of cause-of-death data include more querying of physicians, submission of autopsy summaries to local health departments, encouraging physicians to report additional data after the death certificate has been filed, redesign of the death certificate, and analysis of multiple causes of death after physicians have been instructed to report all of the pathological conditions present at time of death.

5. Programs for improving the accuracy of cause-of-death data should be developed through local demonstration projects in order to improve the practicability and usefulness of the resulting data for epidemiological studies in the degenerative diseases.

ACKNOWLEDGMENT

The assistance of Harri Janssen, John P. Leonard, and John V. Skiff, junior public health interns in the New York State Department of Health, and of the staffs of the local health department and hospitals in the Albany region in carrying out this study is acknowledged.

An official of the Foreign Operations Administration discusses some of the broad considerations which underlie the United States technical cooperation programs as they relate to the health problems in the underdeveloped areas of the world.

Health in Foreign Operations

By JOHN H. STAMBAUGH

THROUGH the Foreign Operations Administration, the United States is working with about 60 other nations to build the mutual security of the free world. We are doing this through joint defense undertakings, through increasing economic strength, and through the sharing of modern techniques.

Under the mutual security program, the defenses of the free nations are growing; the North Atlantic Treaty Organization is now a strong deterrent to Communist aggression in Western Europe. By 1953, NATO had increased the number of its active divisions threefold over 1951 and had more than doubled its aircraft strength. In 1953, the free world's economic strength reached its highest point since the end of World War II.

The United States is cooperating with the peoples of the less developed areas of the world to help build their technical knowledge and skills, with primary emphasis on projects in health, agriculture, and education. Under

President Eisenhower, this cooperation has been increased. More United States technicians are serving abroad than ever before.

Long before the United States Government, through the Institute of Inter-American Affairs and later through the Act for International Development, entered this field of sharing technical knowledge, many private organizations and institutions of the United States were actively working with the people of other countries. Voluntary agencies, foundations, colleges, commercial firms, and church groups were—and still are—carrying out a host of projects abroad. Their work has been notable, especially in the field of health. Through the medical missionary, for example, several thousand dispensaries and hundreds of hospitals have been set up and are daily helping the people of other countries.

The technical cooperation programs of the Foreign Operations Administration, however, are carried out in a different way from the programs of private groups. A church mission may maintain a hospital; a foundation may conduct essential research; an American business firm may provide health care for its employees from the surrounding area in a foreign country. But by their very nature these projects must operate in limited areas. The scope of FOA activity is much broader. This agency works with the governments of the host countries on programs which will eventually result

Mr. Stambaugh is assistant to the director of the Foreign Operations Administration. Presented here are excerpts from his address before the Midwest Conference on World Health, held in Chicago, June 10-11, 1954. The conference was sponsored by the National Citizens Committee for the World Health Organization.

in provision of nationwide governmental service in health and other fields.

In every instance, the United States enters into these cooperative programs only upon request from the individual countries. The initiative for the programs is theirs, not ours: We seek only to help the people to help themselves. Complete responsibility for projects is assumed by the host countries as rapidly as possible. It is important to keep in mind that, while the United States is contributing financially to these joint programs and is sending technicians to help plan and carry them out, the host countries are contributing more than we are, not only in funds but also in personnel and in facilities. Money contributions by the host country, as a matter of fact, average about double the United States' contributions, and in some programs, host-country contributions exceed ours many times—27 times in the health program in Brazil, for instance.

In some of the less developed countries, funds for economic development are made available in addition to technical cooperation. Frequently, these funds supplement technical cooperation by providing supplies and commodities needed to undertake projects or speed up those already undertaken. Where the funds are applied, they permit an increase in the tempo of technical projects.

Guiding principles in the cooperative programs have grown as the programs themselves have developed. In the early days of the health programs in various countries, for instance, matters of immediate emergency were tackled first. The widespread devastating diseases, such as malaria, were attacked on a wide scale. But, as the work proceeded, increasing importance was attached to the development of national health programs to service local areas so that the people themselves could continue to carry on the health work.

Training and Health Education

The United States has given continued attention to the training of local personnel in the techniques and skills necessary to maintain and expand the work once it is under way. This is true for every field of technical cooperation.

Local health workers are trained to the max-

imum extent possible within the country itself, and, in addition, participants in the health programs are brought to the United States for study and for observation of our techniques. Under the Foreign Operations Administration and its predecessor agencies, more than 2,300 technicians in health have received training in the United States. Most of these have returned to take influential positions in their own countries and to help train others in carrying on the programs.

Hand in hand with training has gone the need to acquaint the public of the host country with the programs. In health programs, this has meant developing the acceptance of health practices on the part of the people. It has meant providing health education through every avenue possible, through audiovisual and other information programs, and in conjunction with agriculture and education cooperative programs.

Audiovisual media sometimes do a strikingly good job in informing people about proper health procedures. In one country in the Middle East, during the showing of a film on the care of babies, a husband strode over to his wife and began to belabor her for not having already used the method of baby care which was being shown on the screen.

In another country, in an isolated village, health technicians were surprised to discover one woman—just one—who was taking care of her baby in the manner prescribed by the health team. Inquiry disclosed that her husband had recently been to another village, had seen a film on baby care, and had gone back to see it five times until he had memorized all the procedures so that he could explain them to his wife.

Joint Planning

The Foreign Operations Administration has learned the importance of integrating the different cooperative programs within each country, of relating health projects to agriculture, agriculture projects to health, and so on. Joint staff meetings of the technicians in the different programs in the field have proved beneficial.

In planning one irrigation-project, for instance, it was necessary to see that malaria-

bearing mosquitoes did not breed in the canal waters. It was necessary also to use means for the control of snails which are host to a debilitating disease that attacks humans. Joint planning also permits the closer adjustment of crops to nutritional requirements.

The close relationship between health and education projects is obvious, and, particularly in rural areas, health rules become a primary part of basic education.

The development of joint planning has another benefit. It sets a useful pattern for host countries to follow in the long-range handling of their programs after the United States technicians depart.

Coordination With Other Agencies

In all of its technical cooperation activities, the Foreign Operations Administration endeavors to coordinate its programs with those of the United Nations, the Organization of American States, and other agencies in the field. This close relationship is illustrated by the fact that Dr. John J. Hanlon, chief of the Public Health Division of the Foreign Operations Administration, was a member of the United States delegation to the World Health Assembly at Geneva in May 1954.

Although cooperative projects normally are arranged between the host country and the Foreign Operations Administration, in some instances they include a third party. In Ethiopia, the World Health Organization, for example, works with the Foreign Operations Administration and the Ethiopian Government in a health center organized under the Ethiopian Ministry of Health.

In some countries, in campaigns against diseases, the World Health Organization pays particular attention to control of tuberculosis and venereal disease; consequently, either the Foreign Operations Administration's health programs include fewer projects to combat these diseases or FOA attempts to coordinate possible contributions and activities in these fields with those of WHO.

Coordination of projects applies in all fields. A celebrated example is that of the combined efforts to meet the menace of the desert locust in the Middle East. American, British, and

United Nations workers collaborated with the various governments of the area in dusting by airplane and carrying out other means of combating the pest.

Importance of Health Projects

Health projects are among the first in importance in helping the nations of the underdeveloped areas to strengthen their economies and improve the lives of their people. Strong, able bodies can better open the way to a successful attack on the other problems of a national economy.

Most of the people in the less developed countries make their living from the land. In countries where the people suffer from malaria, they lack the energy to produce in abundance even with improved techniques. Good food may be essential to good health but, on the other hand, good health is a prime requisite in the improvement of agriculture.

The severe drain of disease upon the constructive potential of a nation can be readily dramatized by a few figures. It was estimated a few years ago, for instance, that an annual number of 100,000,000 cases of malaria in India meant that about 9 billion man-days of labor were lost each year. If the inroads made by disease upon productive energies of peoples in the less developed countries of the free world each year were totaled, the figures would be astronomical and almost beyond comprehension.

The conquering of major endemic diseases in these areas thus has its vital economic aspect, as well as a strong humanitarian appeal. It makes better workers of the people and permits them to become more self-sufficient. It also makes of them an increasingly better market in the commerce among nations. They become additions to rather than a loss from world production and trade, and they strengthen the economies of their own nations.

Health projects were among the first begun under our technical cooperation programs. They have reached scores of millions of people all over the world. In Latin America alone, where the work got an early start, more than 20 million persons have directly benefited.

The programs have included measures to solve environmental problems—sanitation, water supply, sewage disposal, and control of insects. They have included the development of health centers, nursing schools, and hospitals. These activities are mentioned to indicate the many different kinds of specialists needed in the field of health. At present, the United States foreign health programs could use at least 100 additional specialists.

The Long-Term Goal

There are both an immediate and a long-term objective in these cooperative programs. The United States wants to help overcome the great scourges that afflict these people, but it wants also to help them establish services for the continued control of disease and for maintaining improved health standards on a permanent basis. These programs help, not only in meeting immediate needs, but also in building the mutual security of the free world.

To achieve the long-term goal, the Foreign Operations Administration is gearing its cooperative efforts to the overall economic development of the host countries. By so doing, the host countries are better able to continue the operations under their own supervision and financing when the techniques have been adequately demonstrated. More and more projects in health, agriculture, education, and other fields are being integrated into balanced programs, with the long-term goal in mind. By experience, it has been learned that although there may be excellent programs in each of these fields, they are not fully effective in helping the host country toward its broad objectives unless they are carefully coordinated.

Nationwide social and economic development cannot take place simply on the basis of functional segments thrown together into a conglomeration of disparate projects, no matter how worthy the purpose of any single project nor how well any one project may be managed. Human and material resources are so closely related to a nation's economic growth and political future that development of all these resources must be integrated as wisely as human knowledge and ability can manage.

If technical skills are to be shared and developed, there must be education.

If knowledge is to be used to build industry, there must be the capacity to produce.

If production is to take place, the workers must have vigor.

Vigor depends upon proteins.

Proteins become available through the efforts of healthy and productive farmers and fishermen.

Education—industry—health—agriculture—each of these separate fields is in itself worthy. Work in each field, however, becomes most effective when geared to operations in all other fields.

One program in which the various factors involved in economic development are given consideration is the area development plan now under way in three provinces around the city of Concepción, Chile. This program permits the concentration of available personnel and funds on a single endeavor rather than spreading them countrywide. Serving as a demonstration activity it provides a base on which other regional developments can be planned.

Another regional program, now operated by the government of the host country, was developed in the Amazon basin of Peru. It includes 6 hospitals, 2 health centers, 4 dispensaries, and a number of motor launches to carry health personnel to outlying districts.

Emergency Food Operations

Closely related to health projects are the emergency food operations of the Foreign Operations Administration. When an economic emergency arose in Bolivia in the fall of 1953, President Eisenhower took action to authorize the sending of \$5 million in surplus agricultural commodities to help meet the food deficit of the country, and another \$3 million was authorized in March 1954.

Emergency wheat shipments to Pakistan were begun in 1953 to counter the threat of famine in the wake of severe droughts. More than 600,000 tons of wheat had been shipped by late April 1954, when the Pakistan Government announced that the crisis had been met. The Pakistan Government reported that the shipments had saved millions of lives.

During the summer and fall of 1953, more than 5½ million food packages were provided for persons in the Soviet Zone of Germany and East Berlin. Nearly a million East Germans crossed the lines into West Berlin to pick up the food. About 4½ million food parcels were distributed in 1953 in Spain, Italy, Austria, West Germany, and Greece, and in many Middle Eastern and South American countries.

These emergency operations, like the health programs, are an essential part of the United States' effort to build strength and stability throughout the free world.

Toward Peace and Progress

All the programs of the Foreign Operations Administration—whether for the sharing of modern techniques, for increasing economic strength, or for joint defense against aggression—combine to help build toward world peace and progress. Our goals are worthy, our methods are honorable and open, our offer of partnership is firm. The United States wants to help other nations to develop their own resources for the good of their peoples and to strengthen their own security and independence. In their strength, we ourselves are strengthened.

Tenth National Conference on Rural Health

The 10th National Conference on Rural Health, sponsored by the Council on Rural Health of the American Medical Association, will be held February 24–26, 1955, in Milwaukee, Wis. Introducing the theme of the conference, "Looking Both Ways," will be an address by Dr. F. S. Crockett, chairman of the Council on Rural Health. Physicians and farm and community leaders will participate in the 3-day program, which is centered around several broad topics: farm and home safety, recreation, family responsibility for health, use of present health and medical care resources, and rural health and world peace.

School Health Education in Dearborn

—A Growing Program—

By FRANK H. JENNE, M.P.H.

FOUR YEARS AGO the school health program in Dearborn, Mich., was primarily service-centered. Since then it has become education-centered, and it continues to grow in that direction.

The same general division of functions between the school and city health departments that existed in 1950 before a study was made is maintained today, except that the schools have vacated the treatment field. Each department has its own nursing staff. The school nurses are responsible for health education and health counseling in the schools, and for followup on school screening programs. The city is responsible for communicable disease control. The city health department provides environmental health service to the schools. It also serves as a channel for the school health department to the specialized services of the State health department. The entire relationship is maintained by frequent conferences between the directors of the two departments and through the Dearborn Community Health Council and the School Health Advisory Council.

Mr. Jenne has been director of school health in the Dearborn (Mich.) Public Schools since 1953. He is also secretary of the Dearborn Community Health Council and a member of the Michigan School Health Association Board of Directors. Before coming to Michigan he was assistant secretary of the Cincinnati Public Health Federation.

In recent years the Dearborn Community Health Council has been making a determined effort to strengthen the city health department's staff and facilities. An advisory public health commission has been established as a result of this activity and several new city nursing positions have been created. The health council's eventual goals include a laboratory, health educator, and a suitable health center for the city department, and a board of health with legal authority.

It was in 1950 that the School Health Advisory Council of Dearborn, including the board of education, school staff members, and parent and community representatives, studied the old program with a group of consultants from the University of Michigan School of Public Health. The study laid for the schools this philosophical footing for the new approach:

"The modern concept of education requires that we accept responsibility for the development of the whole child. Certainly, then, this includes the physical well-being of all children. Since we are an educational institution, our health program should be aimed primarily toward (a) providing that health knowledge which will result in desirable health attitudes and behavior, (b) providing a proper foundation for intelligent choices on the part of the individual so far as his own personal health is concerned, (c) discovering physical defects, and (d) exerting every effort to see that the remediable defects are corrected.

"The school is expected to assume responsi-

bility for the health instructional program and the development of desirable health attitudes and behavior. The school, cooperatively with the parents and family physician and dentist, is responsible also for the detection of physical defects.

"In the matter of treatment, however, it is the policy of the Dearborn city school district that this should be left to the family physician and dentist always keeping in mind that there will be a fringe of medically indigent families for whom treatment assistance must be secured."

The school health department's activity programs—roundup, screening, health appraisal, and topical fluoride—rest solidly on this footing as educational projects. Conversely, the health education program is largely one of activities. Parent as well as pupil participation results in carryover to the home, community support for the program, and material assistance in reducing the workload of the school nurses and teachers. Description of various phases of school health in Dearborn in light of these concepts will indicate the present status in the growth of the program.

Kindergarten Roundup

Roundups are held in the spring for pupils entering kindergarten in the fall and in the first semester for those entering in the second semester. The most successful programs from the standpoint of attendance are those to which parents receive a personal invitation from a parent worker. In one school in a growing neighborhood parent block workers ring doorbells of newly occupied homes and in this way obtain the attendance of parents not known through the school census. Often, this call represents the first contact in a new community and results in the recruitment of new parent-teacher organization members before they become involved in other social or civic activities.

The most successful roundups from the standpoint of program are those that are planned by the building roundup committee with guidance from the principal and nurse, and at which the parent roundup chairman, rather than the principal, presides.

The purpose of the roundup is to provide a happy introduction to all phases of the school

program and to assist parents in preparing children for school. The principal, school nurse, visiting teacher (who is a trained social caseworker), and kindergarten teacher each has a part in the program. The nurse distributes and explains the personal health history form to be filled out by the parent and the health appraisal forms to be filled out by the family physician and dentist. She provides some general information about school health policies and the health needs of the school child. The social hour following the program gives her an opportunity to answer some personal questions and begin to get acquainted with the new parents.

Later, when the mother comes for her enrollment interview with the teacher, she has a "get-acquainted" interview with the school nurse or with the city health department district nurse who conducts the interviews in one building while the school nurse is busy in another. In the interview the nurse may obtain pertinent health information about the child which the parent or physicians have neglected to mention on the health form. She may also find parents who have neglected to have a health appraisal done and encourage them to do so. She may steer them to a community facility such as the city physician if that is indicated.

In this way, 95 percent of the entering kindergarteners had medical health appraisals in 1953-54. Ninety-three percent had complete immunizations. Eighty percent had a dental health appraisal, and 23 percent had topical fluoride applications before coming to school.

The number of fluoride applications approximately doubled, as a result of the city health department's 1953 summer fluoride program for preschool children. The school health department loaned its equipment and helped plan the project. Stations were set up in schools. Unfortunately, the program was not continued in 1954. It may be possible to give the service again in 1955 and enlist the support of the schools' parent health workers in increasing participation.

Screening: Vision and Hearing

The first activity after kindergarten interviews in the fall is vision screening. This is

carried out by the teachers with parent help under the guidance of the nurse. Units in eye health are taught and include such pupil activities as children measuring the light on their desks and preparing posters on eye health. The screening method used is the Snellen "E" chart with plus sphere lenses. Rechecks are made by the nurse before referral. The procedure was worked out with the help of the Michigan State Department of Health consultant and local ophthalmologists. Vision screening is scheduled for the junior primary through grade 6, and again in grades 8 and 10 and the first year of college. In college, the vision screening tests are carried out by a student committee with the guidance of the nurse.

Hearing screening follows much the same organizational and educational pattern as vision screening, except that it is performed by an audiometrist. Pamphlet materials and guides to visual aids for teacher use provided by the State health department are distributed by the nurse to teachers in grades 3, 6, 9, and 12 before the screening begins.

Sodium Fluoride Applications

Preparation for the sodium fluoride program begins with a building committee which may include the teachers, student representatives, parents, the principal, and the nurse. It is the committee's job not only to sell the program to parents and children but also to set up activities that will result in improved dental health practices.

Pupils make posters advertising the fluoride program and display them in the building. The program is often explained to parents at meetings as well as through letters. Second graders write and produce puppet shows and give toothbrushing demonstrations with the large tooth-and-brush models at meetings attended by their parents. After the show, tasty and attractive but healthful refreshments are served. The dental hygienist may be invited in to help a grade 5 class with its project. Eighth graders may collect specimens for lactobacillus counts and send them to the Michigan Department of Health laboratory. In general, the activities of the younger pupils are at the level of drama and imitation, and such children de-

Figure 1. "Mother" brings "child" to "family doctor" for a health appraisal.

light in the mastery of the process of toothbrushing. Older pupils are more interested in the technical and scientific aspects of dental health.

The topical fluoride program has become well known to many parents since its beginning in 1950. Several parent groups have therefore held programs on water fluoridation with speakers supplied by the local dental society.

Slightly more than 90 percent of the pupils in the eligible grades accept the fluoride applications. Eighth grade pupils sign the request form themselves, in addition to obtaining their parents' signatures. This gives them a chance to exercise some responsibility for their own health. The school nurse refers indigent children to the city health department dental clinic for needed care.

Health Appraisal

One of the specific objectives of Dearborn's health education program is to establish the attitude that periodic medical and dental check-ups are an important part of healthful living. After the first health appraisal upon entering kindergarten—or the school system for the first time—additional examinations by the family doctor and dentist are asked for in grades 3, 7, and 10, and the first year of college.

Educational preparation for this event at the lower grades includes the use of visual aids, the nurse or a neighborhood physician as a resource person, and role-playing, by the pupils, of examination procedures (fig. 1). At the high

school level, students prepare and present panel discussions on health appraisal in their English classes. In junior high school, an instructional unit is given by the physical education teacher. This unit seeks first to motivate the student to have an appraisal. It also discusses the physician-patient relationship, the problem of selecting a physician, and quackery. Correlated activities are also carried out by the art, science, homemaking, and "block of time" (English and social studies) teachers.

Orientation programs for pupils entering high school (grade 10) and their parents were developed this past year. They follow to some extent the objectives and pattern of the kindergarten roundup. This activity gives the nurse an opportunity to explain the health appraisal to parents who are no longer active in parent-teacher associations and other school activities. In fact, the orientation programs resulted in considerable parent interest in developing increased parent participation at the secondary level.

The health appraisal program recognizes the fact that junior and senior high school students take increased responsibility for their own health care and that the college freshman is almost solely responsible. In practice, medical appraisals are obtained by 60 to 75 percent of the pupils in grades 3 and 7. This jumps to 97 percent in grade 10 and 90 percent in first year of college. Thirty to forty percent have dental appraisals. One reason for the high 10th grade participation is the reluctance of physical education teachers to permit strenuous activity without the protection of a health appraisal report.

The health appraisal includes a personal health history filled out by the pupil and his parent. Instead of a checklist of procedures, the physician's portion of the form contains questions designed to reveal conditions of which the school should be aware and to bring out specific recommendations for necessary modification of the child's school activities.

Health appraisals for indigent children are regarded as a community rather than a school responsibility. It is the nurse's job to see that school children from indigent families are introduced to the community health resources they need.

Educational Activities

A statement "What Do You Believe About Health Education?" was developed by the school health department staff and instruction personnel (see p. 61). The statement was designed to crystallize a school health philosophy in Dearborn. How this philosophy is carried out varies from year to year and from school to school because of the concept of student-staff planning.

At one building, for example, students must cross a major highway to reach their play area. Despite heavy truck traffic there is no stop light. To reinforce their demand for action, students counted the number of cars and trucks passing the school—some 800 per hour. Staff, parents, and pupils worked on the problem, which was complicated by a question of which of several government units was responsible. Once this problem is solved, attention will be turned to others which can provide worthwhile learning experiences and achieve worthwhile objectives.

In other schools an inadequate breakfast at home is a perennial problem. This is something that requires home-student cooperation. Fourth grade youngsters almost traditionally tackle this problem by putting on a breakfast or luncheon in the school lunchroom for their parents (fig. 2). Usually the menu includes several choices to demonstrate different kinds of good breakfasts. A skit, written and presented by the children, dramatizes the kind of breakfasts they would like to have each day,

Figure 2. Parents join children in eating a "good" school lunch.

Statement on School Health Education

Do You Believe that . . .

- ▶ health education is a continuous experience in healthful living throughout the entire day?
- ▶ health education is a part of every phase of the student's experience in school and out, but improvement of living at school should be our first concern?
- ▶ health instruction should make the maximum use of the health implications inherent in all subject areas?
- ▶ health instruction should recognize personal and group problems of health and actually come to grips with the problems?
- ▶ health instruction should build upon and reinforce the health understandings, habits, and attitudes developed in preceding grades?
- ▶ the health status of students should be given consideration when determining the type of educational program in which they will participate?

- ▶ to establish effective health habits, attitudes, and practices the school must provide a healthful environment?
- ▶ health instruction is an integral part of all of the student's experiences?
- ▶ health instruction is the responsibility of every member of the total staff?
- ▶ health education should result in healthful living, and that correction of defects and mastery of health facts do not necessarily insure healthful living?
- ▶ health instruction extends beyond the course of study and the coverage of material in a basic text?
- ▶ the health program can best be evaluated in terms of behavioral changes?
- ▶ improved behavior is more certain to result when health instruction has been given through the problem-solving approach where students and staff plan and work together?

including some pointed bits of business about the conduct of adults at the breakfast table.

Other schools have tackled the first aid problem. The usual result is a first aid kit and manual written by and for each school and each room. This activity has perhaps helped as much as anything else to establish the school nurse as the school health consultant rather than a finger-wrapper.

The bicycle safety situation became a real problem in one school, especially with conflicting advice from parents and teachers about street versus sidewalk riding and left-side-of-the-street versus right. Parents, staff, and children met with a policeman and other safety experts and wrote their own bike-safety manual. This mimeographed pamphlet got the message across much more effectively than an expensively printed manual prepared by experts could have done because it was written by those who use it.

Halloween treats of candy—often sticky, unwrapped, and insanitary—got the attention of one school. The result: an attractive leaflet, written and illustrated by the children, listing the kinds of treats they would like to have.

These are but a few examples of the kinds of

health education activities in Dearborn schools. Some of them are classroom activities. Others are sponsored by health and safety committees of the student councils. All of them require planning that involves students, teachers, and the nurse and may also involve parents and representatives of community agencies.

The Basic Text

At first the concept of health education as extending "beyond the course of study and the coverage of material in a basic text" was interpreted as the "beyond" only without "a basic text." Of late, as teachers have seen health instruction needs that remain unmet and as they have seen some of the excellent new texts available, an increasing number of requests for text books have come to the director's office.

During 1952-53, the system's elementary health curriculum committee developed screening criteria to be applied to the several health text series available. One of these criteria calls for a text that will stimulate activities of the sort described in this paper and will not substitute for them a simple reading program. Following the preliminary screening, classroom

pilot studies were made in 1953-54 to determine which series will finally be adopted for use. Carefully screened audiovisual aids and other materials are already available to teachers for enrichment of health teaching and include free materials suggested and furnished by the city health department.

In 1951 a committee was appointed to prepare an improved junior high school health and physical education curriculum. A handbook was prepared and texts selected after 2 years of work and study in which consultants from outside the system participated. Now, after 1 year of use, teachers and principals have submitted their comments on the strengths and weaknesses of the course. Their suggestions are being reviewed by the committee and recommendations for further improvement will be made.

Basically, the junior high school course involves a third of each semester devoted to health classes offered by the physical education instructor best qualified to teach health, with the remainder of the time spent in the gymnasium, pool, or on the playground. These classes include units on physical health and safety, first aid, and personality. Additional units, appropriate to the content of the course in which they are placed, are offered in "block of time" (English and social studies), general science, home-making, and industrial arts.

Work on a senior high school health curriculum has just begun as part of a systemwide overhauling of the secondary curriculum. Students have been polled informally as to their interests and needs. Courses of study from other systems have been reviewed, and a list of specific objectives is in preparation. Each high school now has an active future nurses club of which the school nurse is faculty sponsor. Some excellent health teaching is going on but on a "hit or miss" basis.

The new curriculum will emphasize preparation for family and community responsibilities. Instructional responsibility will be shared by the various departments. Teachers will work, not from a set course of study, but from a resource guide which will suggest several alternative methods and list a variety of available resources for use in achieving each objective.

Staff Organization

The school nurse is the sparkplug of the health education and activity program within each school. The 15 nurses employed by the board of education serve 29 public schools, the junior college, and 8 parochial schools. The parochial schools are served on the same basis as the public schools, but lack the advantage of well-organized parent groups. Each nurse serves from 1,500 to 2,200 children in from 1 to 3 schools. A bachelor's degree is required for employment. The staff is remarkably stable. It has a history of only one or two resignations a year.

The successful school nurse in Dearborn shares the leadership of the health program in her school. She has active committees at work on real health problems—yet she knows better than to organize a committee just because one is suggested in the Handbook for Parent Health Workers. She has an infectious enthusiasm for her job that enables her to pile hours of work on busy principals, engineers, parents, teachers, and children and make them love it. She devotes her noon hours to informal conferences with her teachers, for her conception of a "consultant's" job is "to consult" rather than "to be consulted." She works closely with the visiting teacher and counselor, for she is conscious of the mental health implications of her work. She devotes many evenings to committee and staff meetings.

The 8 city health department nurses and their supervisor hold occasional joint meetings with the school health staff. The school and public health nurses serving the same family are encouraged to consult each other directly rather than through interdepartmental channels.

Besides the nurses, the schools employ three dental hygienists, a dentist who gives professional supervision to the fluoride program as required by law, an audiometrist, and the director.

The city health department's sanitarians make frequent inspections of the schools, with special attention to the food service and swimming pool areas. The director of school health analyzes accident reports to find correctable safety hazards.

There is no school physician. Medical advice

is provided as needed by the president of the Dearborn Medical Society, the city health officer, and the city physician.

These physicians, together with the system-wide parent health chairman and representatives of the Dearborn Dental Society, members of the board of education, teachers, principals, school administrative officers, and parochial school, school nursing, and community agencies sit on the School Health Advisory Council, which meets once a month to consider citywide school health problems.

Dearborn also has a well-organized and active community health council in which both school and city health department staffs participate.

Health and physical education policies were last revised and published in 1951. These are interpreted for the staff in the School Nursing Manual, a looseleaf publication that is under constant revision by the staff and the director. In addition, bulletins covering each phase of the systemwide program are issued each year at appropriate times through the offices of the assistant superintendents.

The school health department has a consulting and advisory, or staff, function. Line authority begins with the superintendent and extends down through the classroom teacher.

Policies are developed cooperatively by the line and staff organizations and placed in effect by the line.

For example, a parent and a nurse called the attention of the director to flaws in the system of notifying parents when cases of communicable disease occur in the classroom. The problem was discussed by the School Health Advisory Council, and a committee including a principal, nurse, parent, the city health officer, a representative of the medical society, and the director of school health drew up a recommended procedure including several form letters of an informational nature to be sent to parents. The recommendation was reviewed and approved—first, by the council; then, by the superintendent and his staff, who sent out a bulletin placing the new procedure in effect.

Under this plan of operation each group concerned has a voice in the development of policy, but the authority for implementing policy remains with the line. Much confusion is thus avoided.

The devotion of the health staff and the active cooperation of the board, the administration, parents, and teachers, rather than the pattern of operation, make it possible for Dearborn's school health program to grow and flourish.

Venereal Disease Postgraduate Course

The 23d venereal disease postgraduate course will be given at Tulane Medical School from January 31 through February 4, 1955, under the cosponsorship of the division of graduate medicine and the Public Health Service. The 1-week course accredited by the American Academy of General Practice covers the latest developments in diagnosis, treatment, and management of the venereal diseases and is open to all physicians. Application for enrollment should be sent to Dr. Clifford Grulee, Jr., director of the Division of Graduate Medicine, Tulane University of Louisiana, 1430 Tulane Avenue, New Orleans, La.

research progress report

In reporting the progress of hypertension research assisted by research grants of the Public Health Service, Dr. William H. Stewart prepared for the National Advisory Heart Council, and for limited distribution, a detailed and documented account describing these studies and their relation to the origin, process, and treatment of hypertension. This brief

summary of the investigations was drawn from Dr. Stewart's original report.

At the time of documenting the studies, Dr. Stewart was with the Grants and Training Branch, National Heart Institute. He is presently chief of the Heart Disease Control Program, Division of Special Health Services.

High Blood Pressure

IN THE PAST 5 years, approximately 2.5 million dollars from National Heart Institute appropriations has been granted for 30 research projects on high blood pressure and related fields. About 2 million dollars of this amount is employed by 21 still active projects.

The work pursued by these investigations has been a major influence in (a) encouraging additional extensive and intensive study in what was 5 years ago a peculiarly neglected field; (b) helping to bring about a change of attitude from one of near-hopelessness to one of optimism that hypertension can be managed; and (c) developing better treatment for more patients.

Investigators working on the problems of hypertension are pursuing many avenues in their research, motivated by certain general concepts. The following comments offer a crude frame into which to fit the pattern of NIH-supported research in this field as one element in the total picture.

High blood pressure, or hypertension, is the result of a disease—possibly systemic—directly affecting the blood vessels, from which the heart may ultimately suffer.

Arterial high blood pressure can be caused by or associated with a variety of disorders, but the full causes of essential hypertension, which constitutes the bulk of cases, are unknown. This type of high blood pressure is defined by

many investigators as a persistent abnormal elevation of diastolic blood pressure (the blood measure while the heart is filling) secondary to increased resistance in the peripheral vascular system—the body's bed of small and minute arterial vessels. Since it is generally believed that the abnormal elevation of diastolic blood pressure represents an effect instead of a cause, the core of the problem is the mechanism of increased peripheral resistance.

The following facts illustrate the importance of high blood pressure:

Thirteen percent of the deaths from cardiovascular disease in the United States are definitely due to high blood pressure. Many more deaths which cannot be strictly classified are attributable to hypertensive causes. An additional 30 percent of heart disease deaths cannot be accurately classified as due to arteriosclerosis or hypertension, respectively, but they are due to one of the two, or both.

Of the estimated 10 million persons with some form of cardiovascular disease, fully 4,600,000 have high blood pressure. Of the young men examined by Selective Service during the years 1940-44, 165,000 were rejected because of high blood pressure.

Hypertension is far more common in women than in men, by a ratio of about 2 to 1. On the other hand, hypertension is less frequently fatal for women.

High blood pressure causes a progressively increasing amount of disability after middle life.

The majority of the research grants projects have been aimed toward finding the process by which the peripheral resistance is increased or toward finding a means of nullifying the increased peripheral resistance as therapy for this disease. Currently, several possible processes are under investigation. The studies can be classified roughly as therapy of hypertension, experimental hypertension, and clinical hypertension.

Therapy of Hypertension

Studies supported by the National Heart Institute on the therapy of hypertension chiefly have examined three general techniques: drugs, surgery, and diet.

An increasing variety of both new and old drugs has been under study in the past 4 or 5 years. The rapidly increasing use of some of these drugs by physicians reflects the progress of the research which found the drugs, screened and tested them, and developed their clinical use.

In view of the fact that as recently as 5 years ago there were no drugs especially satisfactory for treatment of hypertension, it is not surprising that the ideal agent has not yet been found. It is even too early to determine fully the benefits from drugs presently in use. High blood pressure is in many cases a 20-year to 25-year disease. The newer drugs, such as the Rauwolfias, have been in use less than 5 years. It can be said that many patients have been greatly helped, symptoms relieved, and useful living restored for some length of time. But a drug is not yet available which affects only the mechanism causing an elevated blood pressure, which remains effective for a long time in a given dose, and which has no bad side effects or reactions.

Surgical and dietary therapies are being improved and are continuing to be used, though perhaps not as much as in the past. At no time, however, has surgery been employed as extensively as diet therapy, which continues to be useful.

Contemporary surgical treatment consists of removal of a diseased kidney suspected of being

the cause of hypertension, removal of an endocrine tumor, correction of coarctation of the aorta, or sympathectomy. Sympathectomies—operations on the sympathetic nerves designed to reduce blood pressure—are of two types: the total sympathectomy, which aims to remove functionally as many sympathetic ganglia as feasible (those nerves adjacent to the spinal column which are linked to and control the diameter of blood vessels), and partial sympathectomy, which restricts the surgery to specific nerve areas. Each denervation differs in procedure, area, and response.

Diet therapy usually falls into 1 of 5 groups: (a) low salt diets, (b) low protein diets, (c) low cholesterol diet, (d) low caloric diet, (e) rice diet.

Experimental Hypertension

The study of any disease is greatly facilitated if the disorder can be produced easily in experimental animals and then manipulated more or less at will. Consequently, much work is done in experimental hypertension, the production and study of this disorder in animals. This work includes studies of the factors which will modify the "experimental" disease once it has been produced and studies of its origin and development in experimental hypertension caused by kidney damage. Much attention is concentrated on the role of the sodium ion and on the activity of renin, an enzyme produced by the kidney. The sodium ion appears to have a central position in the genesis of vascular lesions.

In summary, studies have demonstrated that, by certain manipulations of the kidneys, hypertension in animals can be produced with a fair degree of predictability. Examples of such manipulation include wrapping the kidney with silk, administration of drugs or hormones, introducing infectious organisms, or substituting saturated salt solutions for drinking water. Although reports indicate considerable progress, the exact organic action of the kidney in this experimental animal hypertension is still undetermined.

Extensive investigation of the exact role of the secretions of internal glands in the production of hypertension and their relationship to

other mechanisms also have been productive of much useful knowledge, although it is not as yet decisive.

In particular, research has directed attention to secretions of the adrenal cortex and an anterior pituitary preparation. Removal of the adrenal glands had a striking effect on hypertension in nephritic rats injected with cortisone, if they were well nourished.

Grant-supported investigations of the role of nervous and psychological mechanisms in the origin and development of experimental hypertension have been directed mainly to human subjects because investigations of these stresses in experimental animals have yielded too little useful information. Even in man such studies are extremely difficult because they are affected by a multitude of variable factors. Nevertheless the few studies reported under grant support indicate that nervous and psychological factors must be considered in the complex process of hypertension.

Limited evidence indicates that persons prone to hypertension induced by nerves tend to give a positive skin reaction to injections of histamine. Such a test may help to distinguish such patients from those affected more by glandular or kidney action. Psychological tests and psychiatric interviews also may prove useful

for this purpose, in view of results obtained from a study of college women.

Clinical Hypertension

Clinical investigations have been directed at discovering changes in function and composition of the body occurring in humans during the course of hypertension. In these studies several substances found in the blood are investigated as possible factors causing or maintaining elevations in blood pressure. Among these are:

Serotonin. A material normally found in the blood and taking part in the mechanism of blood clotting, but also a powerful constrictor of blood vessels.

Pherentasin. A highly active constrictor substance rarely present in the blood of mammals but isolated in the blood of hypertensive patients.

VEM (vasoexcitor material). A substance produced by the kidney to maintain blood pressure during shock.

Corticotrophin (ACTH) and cortisone. Hormones produced by special glands of the body that help regulate body function.

Epinephrine and nor-epinephrine. Hormones produced by the adrenal glands that act in controlling heart rate and blood vessel tone.

Dr. Hugh Rodman Leavell

Hugh Rodman Leavell, M.D., Dr.P.H., was chosen president-elect of the National Health Council by its board of directors in December 1954. He takes the place of T. Duckett Jones, M.D., who died on November 22, 1954.

Dr. Leavell, recently the president of the American Public Health Association, has been professor and head of the department of public health practice of the Harvard School of Public Health since 1946. He will succeed to the presidency of the council at its annual meeting in March 1955.

The membrane filter technique described holds promise for the more extensive use of enterococci as indicators of the sanitary quality of water and other materials.

Use of the Membrane Filter Technique To Enumerate Enterococci in Water

By L. W. SLANETZ, Ph.D., D. F. BENT, M.S., and CLARA H. BARTLEY, Ph.D.

ALTHOUGH tests for coliform organisms are still generally used to determine the sanitary quality of water, there continues to be much interest in the use of enterococci as indicators of fecal pollution. Considerable evidence is available to show that the presence of enterococci in water or in other materials may more accurately indicate fecal contamination than the presence of coliforms since it is difficult to establish the fecal origin of the latter organisms. A number of investigators have shown that the enterococci are present in feces, sewage, and polluted water and that they are not found in water, soil, or other materials free from human or animal contacts or contamination.

Dr. Slanetz is professor of bacteriology and chairman, department of bacteriology, University of New Hampshire. Mr. Bent and Dr. Bartley have been associated with Dr. Slanetz, Dr. Bartley as assistant professor of bacteriology, and Mr. Bent as a graduate assistant at the university. Mr. Bent is now at the University of Maryland, as a graduate assistant in the department of bacteriology.

This paper was presented in part at the 54th general meeting of the Society of American Bacteriologists, May 2-7, 1954, in Pittsburgh.

As early as 1900, Houston (1) demonstrated that streptococci are present in polluted waters and appeared to be absent in nonpolluted samples.

When Mallmann and Sypien (2) in 1934 compared the coliform and streptococcus indexes of samples of water taken 5 feet from the shore of a bathing beach, they found that while the coliform indexes and total plate counts did not always respond to changes in bathing loads, the streptococcus indexes did. The streptococci were not found at points free from bathing pollution although the coliform organisms were present in such areas.

Winter and Sandholzer (3) also reported that coliform organisms persisted for a great distance from the source of pollution in water, but that the streptococci did not. They found that although streptococci were present in all samples of human and animal feces tested, these organisms were never found in virgin soils or in soils from wooded areas.

Ostrolenk and Hunter (4) demonstrated that in 37 percent of 51 fecal specimens which they examined, enterococci occurred in equal or greater numbers than did *Escherichia coli*. In the remaining 63 percent of the specimens, *E. coli* exceeded enterococci numerically by from 1 to 5 decimal dilutions. These investigators suggested that the lower number of enterococci in

human and animal feces does not necessarily minimize the potential sanitary significance of fecal streptococci.

Mallmann and Litsky (5), using a dextrose azide broth, were unable to isolate enterococci from soils which were not treated with sewage or animal manure. Although the coliforms were found to persist in sewage-treated soil, the enterococci were found to die out rapidly but not as rapidly as virulent typhoid bacilli.

The lack of suitable methods and media for the detection and estimation of the numbers of enterococci in water or other substances has been one of the chief problems in the use of these bacteria as indicators of fecal pollution. This situation may also account for variations in results reported in the estimation of numbers of these organisms in fecal specimens or in water.

In recent years, much progress has been made in the improvement of techniques for the cultivation of these organisms from various materials. Important contributions have been made by Mallmann (6), Winter and Sandholzer (3), and others (7-11). Because many of these papers have been reviewed briefly by Litsky, Mallmann and Fifield (11), they will not be discussed here.

Mallmann and Seligmann (10) compared standard lactose broth, sodium azide broth (Mallmann), Hajna and Perry S.F. (*Streptococcus faecalis*) broth (Difco), and Rothe azide dextrose broth (Difco) as media for the detection of streptococci in water and sewage. Mallmann and Seligmann noted that the Rothe azide dextrose broth gave the best results for the quantitative determination of streptococci. However, the tubes had to be checked microscopically since gram-positive bacilli might be responsible for turbidity in the cultures. They suggested that azide dextrose broth be used as a new means for testing and measuring streptococci in water, sewage, and shellfish, or in other materials suspected of sewage pollution.

Litsky, Mallmann, and Fifield (11) attempted to develop a confirmatory medium so that an enterococcus index could be obtained in a manner similar to that used for coliforms by the present standard methods procedures for water analysis. These investigators were able

to prepare a medium containing ethyl violet and sodium azide, a medium which they found highly selective and specific for the growth of enterococci. They proposed a new test for enterococci which would use the dextrose azide broth as a presumptive medium and the ethyl violet azide broth as a confirmatory medium. The dextrose azide and ethyl violet broth procedure detected and confirmed 100 to 1,000 times as many enterococci as did the Hajna-Perry S.F. method and the Winter-Sandholzer procedures.

In the present study, our interest was in determining whether, by using the membrane filter technique, methods and media could be developed for the detection and enumeration of enterococci in water. Efficient filter techniques for detecting coliforms in water had been reported by Clark and associates (12), Goetz and Tsuneishi (13), Kabler (14), and others, and there is also a report now in press (15). Thus, it was thought that similar procedures might prove valuable for determination of enterococci.

Materials and Methods

Two types of membrane filter—Millipore (A) and Bac-T-Flex (B)—and the apparatus supplied for both types were used in these studies. The filters were sterilized by placing them between S&S absorbent pads (B), wrapping them in desired numbers in kraft or some other type of wrapping paper, and autoclaving at 121° C., at 15 pounds pressure, for 10 minutes. Then the steam pressure was reduced rapidly to prevent condensation of water on the membranes. When ready for use, the filters and pads were handled by placing them in sterile petri dishes. The filter apparatus was sterilized by autoclaving at 121° C. for 10 minutes also.

For the selective cultivation of enterococci, various media and inhibitory substances were tested for use with the membrane filters. These included: the Hajna-Perry S.F. broth; the Rothe azide dextrose broth; the Winter-Sandholzer sodium azide presumptive broth; the Chapman mitis-salivarius medium; the confirmatory broth of Litsky, Mallmann, and Fifield; and modifications of all these media. Each medium was also tested after the concentration of the nutrient materials was doubled.

Colonies of enterococci on a Bac-T-Flex filter. This picture has not been magnified. One hundred milliliters of polluted river water was filtered through this membrane before it was incubated on pads with the selective enterococcus medium.

To color the colonies of enterococci, 0.01 percent 2,3,5 triphenyl tetrazolium chloride (TTC) was added to the media. A stock solution of 1 percent of the TTC was prepared and sterilized at 121° C. for 15 minutes. Then just before use it was added aseptically in the required amounts to the broth media.

The filtration and cultivation procedures used during these studies were similar to those outlined for determination of coliform bacteria in water (12-15). The various culture media tested were added in 2.2-milliliter amounts to the absorbent pads. The desired amount of water sample or culture material was filtered through the membrane filters using a vacuum produced by a filter pump on water pressure. The filters were then transferred directly to pads containing the test media. These cultures were placed on a shelf about 1 inch above the water level in a covered water bath and incubated at 35° to 37° C. for 48 hours. After incubation was completed, colony counts were made using a stereoscopic microscope magnifying 10 times.

Cultivation of Enterococci on Filters

To determine the efficiency of various media for the cultivation of enterococci on the membrane filters, both dilute suspensions of *Streptococcus faecalis* and samples of polluted water

were employed. Of the different media listed in the preceding section on "Materials and Methods," a modification of the Chapman mitis-salivarius medium proved to be most satisfactory for the cultivation of enterococci on the filters. This modified medium was prepared as follows:

	Percent composition
Tryptone -----	2.0
Proteose peptone No. 3 (Difco) -----	1.0
Proteose peptone (Difco) -----	1.0
Glucose -----	.2
Sucrose -----	10.0
Dipotassium phosphate -----	.4
Sodium azide -----	.04

Final pH 7.0-7.2.

Sterilize at 121° C. for 15 minutes.

Prepare a 1-percent 2,3,5 triphenyl tetrazolium chloride (TTC) solution, sterilize, and add aseptically to above medium just before use to give 0.01 percent final concentration.

After preparation, the base medium was used within a 1-week period.

When this medium is used, the enterococci develop on the filters either as flat colonies, which are light pink in color, or as raised, glistening colonies which are dark red with a pink periphery. At the end of 48 hours' incubation of the cultures at 35° to 37° C., the colonies ranged in size from 0.5 to 2 millimeters in diameter. Although colonies could be detected after the cultures had been incubated for 24 hours, better growth was obtained when the incubation period was 48 hours.

On tests made with polluted river water, colorless colonies of gram-positive bacilli have occasionally developed on the filters. Preliminary tests have indicated that these organisms could be inhibited by the addition of 0.000012 percent ethyl violet to the medium, although concentrations of 0.00012 percent of the dye did not appear to inhibit the growth of the enterococci. However, since the gram-positive bacilli have appeared so rarely on tests made to date, ethyl violet has not been added routinely to our enterococcus medium. We have recently found that 4 percent tryptone and 1 percent yeast extract can be substituted for the proportions of tryptone, proteose peptone No. 3, and proteose peptone used.

When our medium was used in tests with pure cultures of *S. faecalis*, the colony counts on the filters were comparable to those obtained on tryptose glucose agar plates. As well as supporting good growth of enterococci, this medium proved to be highly selective and efficient for the cultivation of enterococci from contaminated water. Potassium tellurite and merthiolate were not suitable as selective agents since they also inhibit growth of the enterococci.

Efficiency for Enterococcus Counts

The efficiency of the membrane filter for the determination of numbers of enterococci in water, as used with our enterococcus medium, was compared with other procedures, particularly with the most probable number (MPN) methods described by Winter and Sandholzer (3) and by Litsky and his associates (11). Tests were made on water samples taken from

Table 1. Comparison of numbers of enterococci in water samples by membrane filter and Winter-Sandholzer techniques, and data on coliform densities

9-----	146	130	150	350

NOTE: Numbers indicate enterococci or coliforms per 100 ml. of water and represent an average of counts on duplicate Bac-T-Flex filters.

a reservoir and six different rivers. The coliform density for these samples was also determined by the standard methods MPN and by membrane filter techniques, which are similar to those outlined by Kabler (14) and are described in a paper now in press (15). Examples of the results obtained with the comparative filter and MPN techniques for coliform density and

the enumeration of enterococci are recorded in tables 1 and 2.

The membrane filter technique always gave higher counts for enterococci than did the Winter-Sandholzer method and gave higher counts than the procedures of Litsky and as-

Table 2. Comparison of numbers of enterococci in water samples, by membrane filter and Litsky-Mallmann-Fifield techniques, and data on coliform densities

Sample No.	Enterococci		Coliforms	
	Filter technique	Litsky-Mallmann-Fifield MPN technique	Filter technique	Standard 5-tube MPN technique

14-----	129	9. 4	1, 060	920
15-----	508	350	320	540
16-----	594	920	290	540
17-----	1, 196	1, 600	200	540
18-----	284	350	80	33

NOTE: Numbers indicate enterococci or coliforms per 100 ml. of water and represent an average of counts on duplicate Bac-T-Flex filters.

sociates for all but three of the samples listed. Thus, when it was used in conjunction with the membrane filters, our selective medium proved highly efficient for the detection and enumeration of enterococci in the water samples. The colonies of enterococci were pink to red in color, and practically all other types of bacteria were inhibited even when 100 milliliters of highly polluted water was filtered through the membranes (see the photograph).

During the study, more than 300 of these pink and red colonies were isolated from the membranes used for the tests on water samples reported in tables 1 and 2. These colonies were first inoculated into the confirmatory ethyl violet azide broth of Litsky, Mallmann, and

Fifield, and then further tested for their ability to grow in 0.1 percent methylene blue milk; in a glucose broth containing 6.5 percent sodium chloride; in a glucose broth adjusted to pH 9.6; and at a temperature of 45° C. All but six of the cultures so tested were identified as enterococci. These six cultures were isolated from red pinpoint colonies which were atypical and rough in appearance. For some of the water samples tested, all of the pink or red colonies which developed on a particular filter were cultured as outlined previously, and all proved to be enterococci.

In addition to its efficiency, the procedure, when compared with other techniques previously developed for the detection of these organisms, saves considerable time, labor, and materials.

Although the counts for enterococci were comparable on both types of membrane filters, the colonies could be counted more easily on the filters with the 8-mm.-square grid markings (B) than on those with the 3-mm.-square grid (A). Because the former filter is also the more flexible and durable of the two types, it was used for the majority of tests reported here. Also, the apparatus supplied by its manufacturer had the advantage of providing a larger filtration area on the surface of the membranes.

Although the numbers of coliforms were generally greater than the numbers of enterococci in the water samples tested, enterococci were detected in all samples containing coliforms except one. This was a sample of river water which had a low coliform index. The coliforms as determined by the filter and the standard methods MPN procedures were in good agreement. Further studies are necessary to establish the significance of the numbers of enterococci as compared with the significance of the numbers of coliform bacteria in the determination of the sanitary quality of water. However, it would appear that the medium and filter technique described in this paper provide a relatively simple and efficient method for the quantitative determination of enterococci in water or other materials. By use of this procedure, tests for these bacteria may thus prove to be more reliable for establishing the sanitary quality of water and foods than have tests for coliform organisms.

Summary

A highly selective and efficient medium has been developed for use with membrane filters in the detection of enterococci in water. With this membrane filter technique, the counts for enterococci were generally higher than those obtained by other procedures. The method affords a relatively simple and direct means for the determination of the numbers of enterococci in water or in other materials.

East Coast Migrant Conference Report

Leaders from 10 east coast States and representatives of public and private groups working directly with migrant families met in Washington, D. C., during May 17-19, 1954, to work out steps that will lead to better health, schooling, and security for the children of migrants—and, to some degree, for their families. The movement of seasonal farm workers has long created problems, both for the migrants and for the communities where they live temporarily.

Conference participants explored many areas in which they thought action was needed. Health questions were concentrated on such subjects as health records, environmental sanitation and housing, and financing of health services. In the short time available, the conferees sketched out a general guide for action and for further exploration. Their ideas and specific proposals, together with individual reports from the States taking part, are contained in a 110-page report which is available upon request to Paul Blackwood, Room 3280, Department of Health, Education, and Welfare, Washington 25, D. C.

The conference was sponsored by agencies of the Department of Health, Education, and Welfare—the Public Health Service, the Children's Bureau, the Office of Education, and the Bureau of Public Assistance. The States represented were Delaware, Florida, Georgia, Maryland, New Jersey, New York, North Carolina, Pennsylvania, South Carolina, and Virginia.

The Commissioned Reserve In Defense and Disaster Health Services

THE DEVELOPMENT of health emergency services in the present era for a population as large and as widespread as that of the United States is one of the most urgent current problems before the health professions. Our experience in prior war periods, although helpful in some respects, has not prepared us realistically for meeting civil defense needs of the future. In fact, had not the superb military defense of our armed forces and those of our allies kept the enemy from our shores, the American people would have paid dearly in needless death and illness because of inadequate civil defense preparation. Today, the situation is vastly more dangerous; the hour is late for orienting our total health forces to the task.

Perhaps the most important and most difficult of the Public Health Service's new national defense responsibilities is the development of an adequate Commissioned Reserve Corps. Since World War II, the Service has been most anxious about the development and maintenance of a reserve commensurate with our existing and potential responsibilities. Although we have had statutory authority for a reserve since 1918, we have never been able to use the mechanism to its greatest advantage.

Our World War II experience proved that to be effective a commissioned reserve should be recruited in peacetime and adequately trained for call to duty in emergencies. The Service had to rely on hastily recruited and superficially trained reserve officers to help

State and Territorial health departments meet their needs for personnel in war areas. We also had to recruit and activate almost overnight many thousands of reserve officers for duty in the Office of Civilian Defense, the United States Coast Guard, the War Maritime Administration, the United Nations Relief and Rehabilitation Administration, and many other war organizations.

In any defense emergency, the total mission of the Public Health Service requires a strong reserve for a variety of activities. In the future, we can readily visualize a greater variety and a larger number of demands than we have known in the past. For this reason, we look upon our present responsibility to the Federal Civil Defense Administration as a long-awaited opportunity to begin the development of a Commissioned Reserve Corps in an orderly fashion—in a preventive fashion, if you will. We intend to combine our commissioning of reserves for civil defense with commissioning for our essential functions in war or other emergency.

The Public Health Service now seeks two primary objectives: first, to augment the supply of health personnel who will be available across the country; and, second, to assure their mobility. Mobility in a national emergency, such as enemy attack, obviously calls for commissioned personnel with credentials which can command transportation and admission through military lines.

Our aim is to augment—not to deplete—the available supply of personnel for duty in public health activities. We will work out with State and Territorial health officers plans for the most effective training and utilization of existing public health personnel through the Commissioned Reserve Corps. At the same time we will recruit actively outside State and local public health staffs. There are many valuable sources which have not been tapped. We have in mind the professional staffs of voluntary health agencies, universities, industrial health and safety services, and insurance companies,

Statement by the Surgeon General based on his annual message to the State and Territorial health officers, Washington, D. C., December 7, 1954.

for example, as well as competent individuals from the appropriate professional and technical groups.

The purpose of the entire program is to provide the organization, training, and mechanisms that will enable members of the health professions to serve to the best possible advantage in civilian services during a national crisis. We will use every available resource to train reserve officers in the health problems associated with atomic, biological, and chemical warfare, as well as in other emergency health problems.

We do not expect to call an officer in the emergency reserve to active duty without his consent, except in the face of a clear and present danger publicly recognized. Such an officer perform-

ing important health duties would not be moved to another area unless the situation clearly justified such a shift. Of course, members of the commissioned reserve may request active duty at any time.

It is to the self-interest of every State, Territorial, and local health officer to promote the development of the Public Health Service Commissioned Reserve, and the wholehearted cooperation of each health officer is strongly recommended in this important Public Health Service activity. Remember, the civil defense objective of the program is to provide indispensable health personnel for the protection of the people in each area should bombs fall or biological attack occur.

PHS Medical Research Grants

Surgeon General Leonard A. Scheele of the Public Health Service has announced approval of 972 grants for basic and applied research in many of today's major diseases. The awards, recommended and approved by the National Advisory Council, are administered by the National Institutes of Health. They were made in December 1954 to scientists in approximately 215 research institutions of the United States. More than half of the awards were for continuation of existing medical research projects.

The grants award program of the Public Health Service covers support of research in the medical and biological sciences, particularly heart disease, cancer, mental illness, arthritis and metabolic diseases, the neurological and sensory disorders, diseases of the teeth and mouth, and certain diseases of microbiological and parasitic origin. Other research projects supported by the program are concerned with the fundamental exploration of metabolic and biological phenomena underlying the causes of most of the prevailing noninfectious diseases.

A full or partial listing of the individual grants, broken down by investigator, project title, amount of support, and research institution is available from the Scientific Reports Branch, National Institutes of Health, Public Health Service, Bethesda 14, Md.

Evaluating Short Health Training Courses Through Content Analysis

By ALLEN D. SPIEGEL, M.P.H., THEODORE I. BLEEKER, M.A., and
SHIRLEY G. BORTOLUZZI, B.S.

THE ADDITION of content analysis to the armamentarium of the health educator provides a valuable tool for evaluating such programs as workshops, institutes, buzz sessions, and seminars. Content analysis can be applied to situations in which the participants freely express their critical opinions of the program without resorting to the use of a detailed evaluation form. The increasing popularity of short programs opens the way for content analysis which more easily measures opinions, attitudes, and feelings that are expressed spontaneously in a written comment. A content analysis reveals information not ordinarily determined by highly structured testing and opinion research methods.

Content analysis has been defined as "... a research technique for the objective, systematic, and quantitative description of the manifest content of communication" (1).

A study conducted by the bureau of public health education, New York City Department of Health, is, we believe, a unique example of

the application of content analysis to an inservice training program for dental hygienists. This report demonstrates how the method is applied and evaluates its use in this type of program. No attempt was made to gain evidence of changes in attitudes or behavior. The analysis was made to determine reactions to the training program.

The Dental Hygienist Training Program

An inservice training program for dental hygienists was planned by the bureau of public health education in consultation with the bureau of public health dentistry. The director of the bureau of public health dentistry requested that the training program have a direct relationship to the work of the dental hygienists and that each hygienist be given a feeling of active participation in the program.

Accordingly, as soon as preliminary outlines for the program were completed, a questionnaire requesting preferences as to subject was sent to all the dental hygienists. The questionnaire was developed by a health educator who had been a dental hygienist and who had knowledge of the group's problems.

One hundred four question sheets out of a possible 138 were returned. The subjects to be included in the group and in the panel discussions were decided on the basis of the returned questionnaires.

Mr. Spiegel and Mrs. Bortoluzzi are public health educators with the bureau of public health education, New York City Department of Health. Mr. Bleeker was formerly a public health educator with the bureau.

Three days were allocated to the inservice program held at a conveniently located health center. At the first session the chairman explained the objectives of the program. The choice of discussion groups in which members might participate on the second day of the institute was explained. Each hygienist was asked to write her first three choices of subject for each session. No one was put into a group not listed as one of her choices. This met the needs of the individual hygienist and provided a feeling of participation.

The afternoon session of the first day consisted of a panel discussion by various professionals of the many factors of a public health dental program. Time was allotted for a question and answer period.

The second day of the program was concerned with work problems. The morning was devoted to a "how-to-do-it" session and the afternoon, to a "talking-it-over" session. How-to-do-it sessions were concerned with teaching skills needed to perform job activities. In these groups, the leaders did some direct teaching, but many opportunities were allowed for the hygienist to participate, share experiences and problems, and find solutions.

Talking-it-over sessions were entirely of a group participation nature. The moderator served as a guide while the participants presented problems and reached solutions.

Each how-to-do-it session was serviced by a combination moderator-resource person, an observer, and a recorder. Each talking-it-over group had a moderator, a resource person, an observer, and a recorder. The recorders were dental hygienists from the groups. The others were public health educators, dentists, nurses, nutritionists, teachers, and social workers.

The "feed-back" sessions on the third day were devoted to discussing the written reports of the recorders. These reports were read aloud for the benefit of the entire group.

The inservice training program for dental hygienists was designed to:

1. Provide the latest professional information for the staff of dental hygienists.
2. Maintain the high professional standards of the staff.
3. Assist the dental hygienists to acquire the educational and professional knowledge and

skill to help them promote, organize, and operate better dental health education programs.

4. Help the dental hygienists acquire an insight into problems arising from interpersonal relationships between lay and professional persons encountered in the course of daily routine.

5. Stimulate discussion, participation, and resolution of problems by the dental hygienists through the group process in the inservice training program itself.

The first two objectives were the only original goals set up by the planning committee and were considered to be long range and continuing. The evaluation committee concluded that the implied aims of the two objectives should be included in a statement of objectives of the program. Therefore, the others were added to the two long-range goals before any evaluation was attempted.

The Method of Analysis

To evaluate the inservice training program, it was not feasible to employ questionnaires for determining preprogram and postprogram skills and attitudes. Nor were statistical methods involving control groups applicable. From the nature of the materials available, it appeared useful to attempt the content analysis technique.

The written reactions of the dental hygienists to each of the 10 group discussions constituted material to be subjected to content analysis. These anonymous comments presented an important opportunity for the evaluation of the degree to which the objectives of the program were attained. Reports of recorders and observers were also used in the evaluation.

Because of the large number of statements, a technique was required to organize the comments according to their relationships to the objectives of the program. Therefore, the immediate aims of the program were reviewed, and categories were determined for each of the goals. These categories represented separate pigeonholes into which each of the statements of the hygienists would be cast for qualitative and numerical examination.

To avoid bias in the analysis, all statements must have a category wherein they may rest easily. Four categories were set up with each

category representing one of the objectives (table 1).

To maintain the objectivity of the analysis and to minimize personal bias, several methods were used. First, indicators were agreed upon for each category. The indicators served as guides to determine the category for each reaction (table 2).

As a second method of maintaining objectivity, every reaction of the dental hygienists was placed in a category separately by each researcher and then recoded at a conference of all three researchers. Thus, 350 statements were categorized, with each of the 10 sessions' reactions kept separate. In some instances there was only one statement on a card to be coded. In other cases there were many statements on the reaction card.

Table 1. Relations between objectives and content analysis categories

Objective	Category
Implementation of classroom skills and knowledge.	{Statements referring to educational and professional knowledge and skills.
Improvement of group leader methods.	{Statements referring to group leader methods.
Discussion of interpersonal relations and participation in the group process	{Statements referring to group participation and feeling.

NOTE. A fourth category was drawn up to encompass statements of a nonspecific critical nature.

By comparing the quality and quantity of statements relating to a particular objective, one has an easily manageable and more significant evaluative measure than would be possible with any other technique which must handle many freely expressed comments.

Analysis

In analyzing the comments of the 166 hygienists given during the 10 sessions (table 3), every effort was made not to change actual quotations of participants in assigning statements to the appropriate category.

Comments presented during two sessions, "how to speak at an assembly meeting" and "clinic dentist," are given in detail. The num-

Table 2. Categories and indicators

Category	Indicator
Educational and professional.	{Specific items of technique and of knowledge.
Group leader methods.	{Authoritarianism, permissiveness, teaching aids, and techniques.
Group participation and feeling.	{Group consensus, sense of identification and participation.
Critical statements.	{Items of a nonspecific and specific critical nature.

bers in parentheses after statements indicate how many times the statement was repeated.

How To Speak at an Assembly Meeting

Knowledge and skills. There were five statements noting the recognition of general knowledge and skills as signified by the statement, "many new ideas." In addition, there were six separate statements referring to specific knowledge or a skill, such as, "motivate children."

Typical comments were: many new ideas on speaking to group (5); ideas on school cooperation (1); know your objective (2); know your audience (2); and motivate children (1).

Group leadership methods. There were three statements recognizing the positive contributions of the leader to the discussion. In opposition were two statements which reflected unfavorably upon the leader's ability.

Observers' statements which supported the favorable reactions were: At no time did the moderator allow time to be consumed by irrelevant remarks; the group never went off on tangents; and the moderator handled the group very skillfully in order to include all members in the discussion.

Reactions were: leader's instruction especially valuable (2); problem area fully covered (1); not enough time to go over mechanics of speaking (1); and problem led us afield of how to do it (1).

Group participation and feeling. All dental hygienist reactions showed cognizance of the group process, including active participation of members, recognition and solution of problems, and the benefits of interpersonal relationships. The group tone was favorable.

Supporting the favorable comments on group tone, the observer noted: The group as a whole

Grand total.....	166	88	41		81		140		350	

and the members individually showed amazing enthusiasm and interest.

The comments were: many good suggestions and ideas brought to surface (2); served as catharsis—getting it off chest (1); group has covered problems and solutions quite well (1); benefited from experiences of group (1); and discussion very stimulating (1).

Critical statements. There are 14 subjective statements reflecting general approval of the session, the workshop process, and the personal benefits gained.

Observer commented that the group felt reasonably adequate solutions were arrived at but that there was not enough time for full discussion.

The hygienists said: enjoyed discussion very much (3); learned great deal from it (3); thought it was profitable (2); workshop idea excellent (3); gotten many good ideas and answers to questions troubling me (2); and it was fine and hope I can follow through (1).

Clinic Dentist

The coded comments of the hygienists participating in a talk-it-over session, "clinic dentist,"

are given for comparison with the above comments from the how-to-do-it session.

Knowledge and skills. Eight statements acknowledged the importance of developing good interpersonal relationships among clinic personnel and the necessity for critical examination of attitudes. Three other statements commented on general and specific techniques of cooperation.

The observer's report reinforced and elaborated the hygienists' statements expanding on the knowledge and skills that were discussed.

Hygienists commented: a matter of personalities and learning to get along (2); relationship between dentist and hygienist should be based on mutual understanding (2); cooperation makes more harmonious relations in clinic (2); develop a closer feeling toward work and co-workers (1); share duties (1); have no specific duties (1); gained information which will help to keep clinic (1); and able to learn from other's problems (1).

Group leader methods. Two comments of a contradictory nature were present: one favorable in a general sense, the other critical, showing a specific fault.

Observer noted that the moderator was skillful in resolving initial resistance. Further, the observer commented that the moderator kept the group on the subject.

Remarks were: too much straying from subject and moderator helpful.

Group participation and feeling. Nine statements mirrored feeling on the value of exchange of ideas, the sense of working together to resolve problems, the opportunities to share experiences, and the value of group discussion. Two dissenting comments noted that the topic was not suitable for group discussion and that the group should have been more homogeneous.

Observer noted that no one was prevented from introducing pertinent subject matter. The observer also noted that participation may have been restricted because of the presence of two dentists and a resource person.

The stated reactions were: problems common to most (2); opportunities for airing personal likes and dislikes (2); discussion group a fine way of learning (1); nice to get together to discuss problems (1); group discussion improves feeling toward work (1); exchanged solutions to personal problems (1); makes us feel we are working together (1); accomplish more with smaller group (1); and topic should not be discussed in groups (1).

Critical statements. The expressions affirmed the value of this type of session. Two further statements continued this theme by requesting more sessions of this type. Six comments of a negative nature regarded the session as having no value. Four of these felt it was the fault of the type of session and two felt the discussion was not useful personally. Two statements echoed the suggestion that clinic dentists should be present to air opinions.

Observer commented that the session had definite value even though solutions were difficult to achieve. The observer also remarked upon the anxiety of the group to continue similar discussions.

The comments were: dentists should be there to air opinion (2); discussion helpful (2); interesting and informative (7); sessions valuable to work (1); should have more sessions (2); can hardly solve problems (4); and not valuable to me personally (2).

The remainder of the groups were treated in the manner previously explained and illus-

trated. Following is a summation of the results of the overall sessions.

Summary

This summation is based on the method of content analysis as applied not only to individual sessions, but also to the program as a whole. Each category summarization represents a compilation of all comments from all 10 sessions in that category.

Knowledge and Skills

Eighty-eight comments were elicited from all sessions covering specific items of knowledge and skill with a low of 2 for the "parent interview" and a high of 16 for "audiovisual aids."

In this category of knowledge and skills, the effectiveness of imparting the information has to be judged on two bases: the quality and quantity of the dental hygienists' comments and the supporting comments in this category by the observer and recorder. Quality refers to the degree of specificity of the comment. Those comments which referred to knowledge and skills in a nonspecific way were put in the category of critical statements. Content analysis alone did not seem to be sufficient for judging knowledge and skills acquired in this program.

Content analysis, however, does prove of benefit in numerically ascertaining comparisons of types of responses. More responses in knowledge and skills were made in the how-to-do-it session than in the talking-it-over session. This would seem to reflect the nature of the sessions.

Group Leader Methods

Content analysis proved most valuable in showing which staff members needed further training in group leadership. For example, in the session of "parent's meeting" there were eight unfavorable comments and none favorable. The nature of the comments indicated that this particular group leader probably needed training in motivational techniques and lesson planning.

The talking-it-over session produced a few comments on group leader methods. This is as it should be, since the session was designed to mute the leader's role and to encourage

democratic group participation. One session, produced nine unfavorable comments in this category. In reviewing the critical statements of this group, they showed that the leader lost direction of the group and did not fulfill the role of moderator. This leader should receive special training in group guidance.

Content analysis will help in the organization of future programs by determining which staff member should participate and which skills should be emphasized in their orientation training.

Group Participation and Feeling

Examination of the data for this category reveals a preponderance of favorable remarks relating to the group process. Significantly, even though group participation was new to many of the participants and therefore not many remarks could be anticipated in this category, the 81 comments showed that the dental hygienists recognized and commented on many aspects of the group process. These comments noted the various phases of group interaction, such as exchange of ideas, recognition of problems, solution of problems through discussion methods, and the good interpersonal relationships developed through this medium.

Content analysis would seem to be an effective tool for determining the intangibles of the group process which would be difficult if not impossible to ascertain using objective measuring devices.

Critical Statements

Statements in this category freely expressed the feelings of the hygienists on the value of the sessions. The majority of comments were favorable and they indicated that solutions were reached and the time spent was worth while. These general statements were interrelated to the other categories and served to reinforce opinion expressed more specifically elsewhere.

Suggestions

For those desiring to use content analysis for evaluative purposes, the following suggestions may be helpful:

1. All reaction forms should be drawn up explicitly to meet the objectives of the program while still giving opportunity for freely expressed narrative statements.

2. There must be a separate category for each objective of the program so that analysis may reveal the degree to which the program has succeeded in its attainment of each objective.

3. Objectivity in the analysis should be maintained through standardization of indicators and through cross checking by various members of the research staff in order to maintain reliability.

Conclusions

It has been demonstrated that the dental hygienists acquired an insight into problems of interpersonal relationships. Further, the dental hygienists appreciated and benefited from the discussion, participation, and resolution of problems through the group process. Content analysis did not show adequately the acquisition of professional knowledge and skills by the dental hygienists. The analysis was not able to measure the objectives of providing latest professional information and maintaining high professional standards, probably because these were long-range intangibles and this method does not readily lend itself to the evaluation of such factors. Generally, the evaluation showed that the program was a success and that the hygienists wanted to continue this type of inservice training.

Sickness as Recorded in Family Surveys

There are many ways to express the extent of deviation from normal health in an observed population, such as the incidence of new cases of illness, the days of illness during a given period, the days of illness per case, and the prevalence of illness at a given time. These and other measures can be expressed in terms of rates or ratios for all cases and for cases of different severities, such as nondisabling, disabling, confined to bed, and admitted to a hospital, together with days per 1,000 population and days per case for cases of each severity. Thus, morbidity from all causes can be expressed in many ways, aside from similar rates and ratios for specific diagnoses.

Detailed data on illness have been collected in six surveys by periodic visits at intervals of 1 to 3 months to households in the general population, covering nearly 100,000 full-time person-years of observation. These surveys made over the past generation by, or in cooperation with, the Public Health Service afford considerable data on 103 diagnoses for all recorded cases, and only about half a dozen less for cases disabling or confining to bed for 1 day or longer. This study represents a detailed analysis of these records of illness in the general population, supplemented by records of hospitalization, particularly of mental diseases, tuberculosis, and a few other chronic diseases.

In the study it was not feasible to follow chronic cases throughout their total duration, so cases and their durations were expressed as "episodes" of illness. This procedure made it feasible to get some idea of seasonal variation by a tabulation by months of onset of such cases or episodes as had their onset during the study period.

No detailed discussion is needed here, but a few summary statements should be made regarding important findings:

1. These studies indicate total annual cases of illness of 1,060 per 1,000 population, or about one illness per person per year. Of these cases, roughly half (565 per 1,000) were disabling for 1 day or longer, and the other half were not dis-

Public Health

MONOGRAPH

No. 25

The accompanying summary covers the principal findings presented in Public Health Monograph No. 25, published concurrently with this issue of Public Health Reports. The authors are with the Division of Public Health Methods, Public Health Service.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, United States Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and the major universities, and in selected public libraries.

abling. Disabling is here used in the sense of causing the patient to be unable to perform his usual duties, such as work, housework, attending school, or other activities for 1 day or longer. Of these disabling cases, 405 per 1,000 population spent 1 or more days in bed because of the illness, and of the bed patients 56.4 per 1,000 population spent 1 or more nights in a hospital. These hospital patients constituted 10 percent of all disabling cases and 13.9 percent of all bed patients.

2. Of all disabling cases or episodes of illness, 13.4 percent were chronic; similar percentages of bed and hospital episodes of illness were 13.8 and 22.6, respectively. The mean duration of disability per acute illness or episode was 10.3 days, as compared with 63.6 days for chronic episodes; however, the annual days of disability per 1,000 population of the 5 surveys was 5,007 and 5,101 for acute and chronic illnesses, respectively, with a total for all cases of 10,108 annual days of disability per 1,000 population, or 10.1 days per person observed.

3. Of the acute disabling attacks, 96 percent were disabling for 30 days or less, as compared with 72 percent for chronics; to reverse the statement, only 4 percent of acute cases were disabled for more than 30 days, but 28 percent of the chronic cases were disabled that long. On the other hand, 24 percent of the acute cases were disabled for only 1 or 2 days, and 18 percent of the chronic episodes were disabled for only that long. Finally, 86 percent of acute cases were disabled for less than 18 days, and 47 percent of the chronic episodes involved less than 18 days of disability.

4. Variation with age and variation with season are shown for total cases of each specific diagnosis, and variation with age is shown for hospitalized cases for as many diagnoses as the smaller numbers justify. Variation with age and sex is shown for bed cases; for a few diseases the rates for women are exceptionally higher than for men, such as those of the thyroid gland, of the gallbladder and liver, appendicitis, neuritis, headache, nervousness, psychoneurosis, arthritis, diabetes, and injury by fall. On the other hand, some diseases had definitely higher rates for men, such as peptic ulcer, hernia, and traumatic lacerations.

5. The respiratory diseases show consistently greater seasonal variation, with peaks in January or February, with ear and mastoid diseases showing peaks also in February. The acute communicable diseases, hay fever, and the acute stomach and intestinal upsets also show large seasonal variation, but episodes of chronic diseases generally show much less seasonal variability.

6. Admissions to short-term general and allied special hospitals have increased rapidly since 1935, hospital days per 1,000 population less rapidly, but hospital days per hospital case have generally declined since 1935, and particularly since 1945. However, increases in hospital admissions and days of care per 1,000 population do not necessarily mean an increase in illness; higher incomes, the budgeting of hospital costs by insurance, and the increase in the general level of living have probably been large factors in the increase of hospital care even without any increase in day-to-day illness in the United States.

A Mental Health Program is Born

By MURRAY GRANT, M.D., D.P.H.

THE DEVELOPMENT of a mental health program in Cattaraugus County, N. Y., has been an avocation of many of the county residents and the county's civic and health organizations during the past few years. A major and tangible result of the community's efforts is a countywide mental health clinic, now established in the Cattaraugus County Department of Health and in operation since May 1954.

Cattaraugus County has a population of 80,000 and is located in the western part of New York State. Its main city, Olean, is situated 70 miles southeast of Buffalo. The county is approximately 40 miles long and equally wide. It is predominantly rural and would not be considered a particularly wealthy county compared with many others in New York State.

It was Dr. C.-E. A. Winslow who said many years ago that "It would be highly desirable for such a county as Cattaraugus to make at least a beginning in the recognition of its mental problems; and this could, perhaps, best be accomplished by providing a psychiatric social worker to serve jointly with the social service staff and nursing staff of the county department of health. Through such a worker the extent of the local needs could at least be visualized and the county prepared to take its part in the development of the future" (1).

Dr. Grant has been commissioner of health of the Cattaraugus County Department of Health, Olean, N. Y., since 1951. He began his public health career in 1950 as assistant health officer of the Baltimore County Health Department in Maryland.

Mental health was recognized as a proper health department activity in the early days of the county health demonstration established by the Milbank Fund. As early as 1926 a psychiatric social worker was employed by the county health department, primarily as a consultant to the public health nurses. Although this experiment lasted only a few weeks, it showed that the importance of mental health in a public health program was recognized, even in those days. The New York State Commission for Mental Defectives has operated occasional mental health clinics in the county, and during 1924 and 1925 made 50 psychological examinations. In addition, Gowanda State Hospital, located just outside the county, has operated clinics within Cattaraugus County. These clinics are still maintained 1½ days a month, but they are now reserved for convalescent patients.

In April 1951, a Mental Health Committee was organized as part of the Cattaraugus County Tuberculosis and Public Health Association. This group became interested in stimulating a mental health education program. It held a number of meetings, distributed pamphlets, had several programs on the local radio station, and prepared news releases for publication in the local newspapers.

This committee proved there was an interest in the field of mental health, and, in March 1952, the committee was reorganized and renamed the Cattaraugus County Mental Health Society. It was still associated with the tuberculosis and public health association. Every possible effort was made to obtain representation from many interested individuals and agencies as well as to insure that the various geographic areas of

the county were represented. The following groups formed the nucleus of the society: county welfare department, Catholic charities, the clergy, county board of health, school authorities, parent-teacher associations, children's court, chamber of commerce, and the county medical society. In addition, members of the tuberculosis and public health association and the county health department became a part of the society. A factfinding committee was appointed at the initial meeting and asked to get information on mental illness and facilities in the county. This committee sought from various agencies and groups in the county answers to a number of questions such as:

1. What is the mental health need as determined by the number of patients in mental hospitals?
2. What preventive and treatment facilities are available locally?
3. What local professional groups are concerned with mental health?
4. What other community agencies or organizations influence mental health?

At the next meeting of the mental health society in May 1952, five committees were formed to investigate the various phases of the mental health situation which had been uncovered by the factfinding committee. These five committees had one of the following functions:

1. To investigate the need for a mental health clinic in the county.
2. To determine the need for, and practicability of, a psychiatric wing in one of the local hospitals.
3. To ascertain the best ways in which to disseminate mental health information.
4. To explore the possibilities of integrating mental health principles into the local governmental agencies.
5. To determine whether it would be desirable to promote local mental health groups in each community.

Clinic Activities to the Fore

Each of these committees met to discuss the problems to which it had been assigned. At the next general meeting of the society in September 1952, it was clear that the group had become particularly interested in mental health

clinic facilities. This was something tangible. This was a project which could lead to a sense of proud achievement and could form a base from which to approach the problems the group had found.

I need hardly interpolate that the county health department and the tuberculosis and public health association played a leading role in all of the foregoing activities and helped stimulate the mental health society by pointing out the possible avenues for exploration. At the same time a considerable number of news releases were drawn up to insure that the public was kept well informed of all developments.

The Committee on Mental Health Clinics became very active. Extensive inquiries and investigations were made. Speakers were obtained to talk on the subject at public meetings to which various civic officials were invited. People from all ends of the county attended the meetings.

The committee reported that Cattaraugus County had very little in the way of facilities to which the emotionally disturbed could turn. They could, of course, be committed to a mental hospital for observation and treatment. But this procedure was accepted with reluctance. There was no psychiatrist in the county, and, in general, residents of Cattaraugus County had to travel up to 70 miles for psychiatric care. Very few did this. The New York State Department of Mental Hygiene operated a traveling child guidance clinic one day a week. However, this service was very limited and did not, in fact, cover much of the county. Moreover, very little treatment was offered, and, since none of the clinic team members resided in the county, it was often difficult to reach them. In addition to this facility, the closest mental hospital, which was located just outside of the county, operated a clinic for adults 1½ days a month. However, this clinic was confined chiefly to patients convalescing from care at the mental hospital. The committee concluded that a mental health clinic was needed in Cattaraugus County. The remainder of the society agreed.

In the meantime, both the health department and the tuberculosis and public health association were active in stimulating local interest

in the project. While the association promoted and prepared mental health exhibits for the county fair, the health department was busy publicizing the matter widely. A mental health nursing consultant from the New York State Mental Health Commission was engaged to provide inservice training for the public health nurses. In addition, both organizations worked together in promoting the establishment of citizens' health committees in two communities in the county. These committees also helped inform the people of the area of the importance of mental health.

Funds and a Home

The next problem was to determine how a clinic could best be established and how it should be organized and administered. Possible sources of funds were considered—the New York State Mental Health Commission, the schools, public subscription, and the county health department. At another public meeting it was finally agreed that the clinic could best be organized and administered as a division of the county health department. Accordingly, in May 1953, the chairman of the county mental health society asked health department officials if they could include an appropriation of \$30,000 in the department's budget for the year 1954 to establish a mental health clinic. This amount included funds for a full-time psychiatrist, clinical psychologist, psychiatric social worker, and a secretary. Although appropriated from county funds, 50 percent of the amount would be subject to State reimbursement.

In the meantime, health department officials had discussed the proposed clinic with the county medical society, with the county board of health, and with some of the prominent members of the county board of supervisors—the department's appropriating body.

In September 1953, the county board of health passed the health department budget, including in it \$21,240 for a mental health clinic for the year 1954. The difference in this figure and that suggested by the mental health society was due chiefly to the fact that the psychiatrist was to be employed on a part-time instead of

a full-time basis. A psychiatrist employed part time, it was suggested, could work 3 days a week for the health department and devote the remainder of his time to private practice. It was pointed out that not only would this arrangement be more likely to appeal to a psychiatrist, but also it was believed unlikely that the board of supervisors would pass a budget containing a salary high enough to attract a full-time psychiatrist. Plans to house the clinic in the health department and make other use of existing facilities helped keep the budget low. This, then, was the budget submitted to the county board of supervisors for their consideration.

Much now remained to be done to show members of the board of supervisors and the public at large why the mental health clinic was needed and how it would operate. A tremendous amount of effort was used by members of the mental health society and others through personal contacts, talks, and preparation of newspaper releases. In October 1953, the county medical society sent a resolution to the board of supervisors endorsing and recommending the establishment of a mental health clinic within the health department as proposed in the 1954 budget. This budget was adopted in November 1953 by the board of supervisors.

A psychiatrist, who met the required qualifications and was also socially acceptable to a fairly rural community that is not subject to much change was obtained and began work in the clinic in April 1954. Soon afterward all the other members of the clinic team were appointed, and the clinic actually commenced operation in May 1954.

In Operation

The people in the county had shown a great deal of interest in the clinic. To retain and advance that interest an advisory committee was formed in March 1954 to help develop policies and procedures for the mental health clinic and to assist in interpreting the clinic's functions to various agencies and communities in the county.

The advisory committee was composed of representatives of the welfare department, children's court, Catholic charities, school authorities, the medical society, the mental health society, Alcoholics Anonymous, industry, the

tuberculosis and public health association, the county board of health, and the clergy. Actually, many of these persons formed the nucleus of the mental health society. The committee had its first, and very successful, meeting in April 1954.

In the first 3 months of operation there were 228 visits to the mental health clinic. The patients, both children and adults, were referred by physicians, the welfare department, clergymen, schools, public health nurses, and the children's court. Some of them came without referral. In general, the clinic sees all comers, although persons under the age of 16 are not interviewed until a parent has been seen. All patients have an initial orientation interview with the psychiatric social worker, who determines whether the patient requires psychiatric and psychological examinations. After completion of a psychiatric examination, the members of the clinic team meet to discuss the case and formulate plans for treatment.

The clinic has just started, of course. Much work remains in combining the clinic service

with an education and training program for physicians, nurses, school personnel, and others. We are headed in this direction, but we realize that it will take time. Already one of the community health committees mentioned previously has formed a mental health committee to work with the mental health clinic team, and I feel sure that many others will follow.

At present, we are in the process of interpreting the intake policies and procedures for the clinic to other agencies and groups. We hope to bring other members of the health department and other agencies and individuals into close association with the mental health clinic team so that the mental health clinic will form the nucleus of a complete mental health program that will reach into all areas of the county.

PHS Advisory Council Appointment

Dr. Currier McEwen, dean of New York University College of Medicine since 1939, has been appointed to the National Advisory Arthritis and Metabolic Diseases Council. Dr. McEwen is chairman of the Medical and Scientific Committee and a board member of the Arthritis and Rheumatism Foundation. He is also chairman of the Medical Advisory Council of the Masonic Foundation for Medical Research and Human Welfare and co-chairman of the New York University Study Group on Rheumatic Diseases. Dr. McEwen obtained his medical degree at New York University, and he was awarded the honorary doctor of science degree by Wesleyan University and by Marietta College. He served his internship at Bellevue Hospital in New York City. He was associated with the Rockefeller Institute from 1927 to 1932 and then went to New York University College of Medicine to become assistant dean and instructor in medicine.

Representing Pennsylvania's third annual health conference, held in August 1954 at State College, Pa., are the papers summarized in this section. Four deal with chronic illness and one with the work of the local health laboratory.

Pennsylvania Health Conference

Cardiovascular Health Center in New York

In coronary heart disease and hypertension, foremost among chronic disease control problems, much excellent research is being done to improve our understanding of the basic mechanisms causing the conditions.

Keys, for example, has gathered much evidence for the theory that a high proportion of fat in the diet is related to the development of atherosclerosis of the coronary arteries. He has demonstrated that countries having a high proportion of fat in the diet also have high death rates from degenerative heart diseases. Morris and co-workers suggest that occupational groups associated with physical exercise have lower death rates from coronary heart disease than do those who work at more sedentary pursuits. Gertler and associates have mar-

shalled evidence that persons of the mesomorphic-endomorphic body type seem especially prone to develop coronary heart disease. Levy and associates have pointed out that hypertension develops in individuals who have labile blood pressure or tachycardia. The relationship of obesity and hypertension is also well known.

For a long while official health departments have been waiting for basic studies to give answers which can be translated into control programs. Meanwhile most health officers have contented themselves with some peripheral activities in the heart disease field, such as postgraduate education of physicians and nurses, provision of cardiac consultants for certain clinics, and the extension of public health nursing services to cardiac patients. A few departments have become interested in rehabilitation of the cardiac patient, largely a problem of the patient's attitude and that of his employer toward the disease.

Health Department Job

But none of these measures is meeting the main issue. Knowledge required for the control of disease has often preceded that concerning its etiology and pathogenesis. The public health physician has behind him years of experience in controlling diseases before their cause has been determined. This has been true of cholera and typhoid fever, the prevention of leukemia among radiologists, and the control

By George James, M.D., M.P.H., assistant commissioner for program development and evaluation, New York State Department of Health, and associate professor of preventive medicine and public health, Albany Medical College, New York.

of diabetes. Adult heart disease may present more of a challenge, but this should serve mainly to give it a high priority for our public health resources.

One method of approach open to official health agencies is a study of the epidemiology of coronary heart disease and hypertension. Departments of health have teams of trained epidemiologists, statisticians, and, recently, social scientists. They possess the legal responsibility to take necessary measures to control prevalent diseases. Health departments, furthermore, are the legal custodians of morbidity data, and through their liaison with medical and other professional societies and their association with industrial health programs, they are indeed in a fortunate position to pursue such studies.

But the official health agency has a far greater responsibility than the undertaking of discrete epidemiological studies. It must mobilize its resources more completely for a large-scale, long-term study of coronary heart disease and hypertension.

New York Study

In New York State it was decided that the official health agency is not only able to undertake long-term longitudinal studies, it is the organization best able to make them. This decision led to the establishment of the cardiovascular health center program in February 1953.

The cardiovascular health center has been established as a part of the Albany Medical College under contract with the New York State Department of Health. The dean, professors of medicine and radiology, and the associate professor of medicine for cardiology are members of the governing council. The close and continuous association of the project with a medical school makes available to it all the clinical specialties and preclinical science departments of the school.

Another essential of such a project is close and continuous association with the professional personnel of the State health department. The governing council of the cardiovascular health center includes the commissioner of health and the assistant commissioners of medical services,

laboratories and research, and program development and evaluation. In addition, at a series of training and discussion staff meetings, all the bureau directors were asked to devise ways in which their programs could assist the heart disease activities and goals of the cardiovascular disease center and how, in turn, the center's activities could assist their programs. The program development and evaluation unit maintains continuous liaison between the center and the other programs of the State health department. Statistical service is provided by the State health department.

A third criteria is a suitable stable population of sufficient size, willing to cooperate in this type of study. The male civil service population between the ages of 40 and 54 in the Albany area, numbering about 2,000 individuals, was selected as a group of sufficient size, stability, and susceptibility to give statistically significant results under a program of long-term study of the cardiovascular center. Eighty-seven percent of those contacted have received the first examination on a voluntary basis and have agreed to follow through the periodic examination program at the center. Participants with significant medical findings are referred to their private physicians for treatment.

An attempt is being made to discover how to diagnose coronary heart disease and hypertension in the earliest possible preclinical phase. This diagnosis will make epidemiological studies of these conditions more effective by broadening the number of conditions that can be listed as early stages of these diseases.

Diagnostic Tests Applied

The center is applying existing diagnostic tests periodically to the same population. As cases of coronary heart disease accrue, we may then search back through the examination records in the hope of discovering which findings suggest the development of degenerative heart disease. Keys has suggested that more attention should be paid to the measurable variations among so-called normal individuals, since some of these differences may be significant in predicting the development of later chronic illness. Preliminary blood pressure and weight measurements made at the center on 1,051 par-

ticipants in the study suggest that the higher blood pressures tend to occur more frequently among persons of greater body weight.

Among the tests used by the center is an electrocardiogram following measured physical stress administered either through the Master's stairstep test or the treadmill. Of the first 1,072 participants studied, the diagnosis of coronary heart disease was made in 27 cases in the preliminary findings. Nine were in groups diagnosed by history alone, 10 by history plus electrocardiogram, and 8 by electrocardiogram alone. In the latter group, three cases were discovered solely through the use of the stress test.

In this type of project the applicability, reliability, and validity of existing diagnostic tests for heart disease should be studied in order to discover which are suitable for more general application to the community. This information, too, will facilitate future community epidemiological studies. Tests made at the center indicate that cardiac enlargement can be measured by both X-ray and electrocardiogram and that each of these techniques discovers a group not discernible to the other. Studies are also proceeding on the use of skinfolds in the determination of obesity and on the cost, availability, speed, and safety of the various detection tests proposed for wider usage.

The cardiovascular health center must serve as a core for research teams interested in performing both basic and applied research. Thus, it is working in cooperation with the new protein laboratory of the New York State Health Department, which has ultracentrifuge, electrophoresis, and blood fractionating equipment for the study of lipoproteins. The State laboratory, with its long experience in immunology, can study possible parallels between this field and the biological mechanisms responsible for chronic disease. The bureau of nutrition of the department is investigating the obesity measurements and diet histories of participants. Social scientists in the department are interested in social and emotional stress and heart disease. Epidemiologists are taking retrospective histories on hospital patients to check the association between clinical heart disease and certain factors. Members of the Albany Medical College department of medicine

are engaged in studies on basic physiological mechanisms associated with the cardiovascular status of the participants.

Progress in State Rehabilitation Program

PHR Some time during our lives each of us has seen someone fall victim to a serious crippling disease or disabling injury: some we remember as "shut-ins," while others we hazily recall as being in the hospital for a long time. Some get around a little, trying to work occasionally at odd jobs; the others are confined to a bed or wheelchair.

Many of these people just seem to disappear from our personal lives. They join that army of disabled people who fill the chronic disease hospitals, the back bedrooms of thousands of homes, the mental institutions, the nursing and convalescent homes, the institutions for the aged and infirm, and homes for the poor. Physicians and nurses know about them, for the institutions are so crowded that applicants and their families must be carefully screened and checked to make sure that only the most urgent cases are accepted.

Decade of Progress

We have recently closed a significant decade of progress in rehabilitation in which we have discovered that many men and women formerly destined to lead a life of dependency can be rehabilitated. The way has been pointed toward a more complete approach to the problems of the disabled person. No longer do we consider the social, physical, or economic effects of a disability as separate entities in an individual.

By Floyd L. Kefford, chief of physical restoration, bureau of rehabilitation, Pennsylvania State Board of Vocational Education.

Rather we see the many phases composing the individual as interrelated, one with another—his job, his family, his physical condition, his place in the community, his desires, and all of the attainable factors comprising the entire person.

It is also possible with the new drugs, the improved techniques of surgery, better hospital facilities, the establishment of comprehensive rehabilitation centers, and the employers' realization that ability, not disability, counts that thousands can leave their wheelchairs, their hospital beds, and their homes to become self-sufficient.

Ten years ago who could foresee that a paraplegic mother bedfast in her home could be physically improved enough to resume the responsibilities of raising her children and making a living for her family; that a boy so badly crippled with arthritis that he was unable to bend any joints except those in his arms and hands could become a successful watch repairman; that a 45-year-old railroader, forced to give up his chosen vocation because of a severe cardiac condition, could undergo surgery enabling him to return to full employment.

Maximum Help

Pennsylvania has demonstrated that these citizens can be improved physically and prepared vocationally for employment through the services of the bureau of rehabilitation, a State agency under the supervision of the Pennsylvania State Board of Vocational Education. With its trained staff of counselors, medical consultants, and full complement of services, which include medical and psychological evaluation, surgery, hospitalization, appliances, vocational training, and maintenance, the bureau is prepared to help chronically disabled clients achieve maximum rehabilitation.

Probably the most important single factor in the development of Pennsylvania's rehabilitation program during the past 10 years was the inclusion of physical restoration as a part of the services offered by the bureau of rehabilitation through enactment of Public Law 113 in 1943. By the passage of this bill the Federal-State rehabilitation program definitely joined hands with the men of medicine. Their knowl-

edge of how physical defects can be reduced or corrected plus the counselor's knowledge of how to prepare a client for a suitable vocation made it possible to achieve maximum rehabilitation for the client with a chronic disability.

Before this phase of the program was developed the counselor encountered many problems. He was required to "rehabilitate around" a disability which could have been reduced or corrected with good medical services. A young girl with an unattractive clubfoot supported with a brace, for example, was helped in her mental adjustment, trained for suitable work, and placed in a remunerative job, but the chronic physical condition remained. Today, through the physical restoration services available in the bureau's program, such a case would be treated differently. The foot could be amputated and the client fitted with an artificial limb. Taught to use it and to dress and walk like other girls her age, she would have little left of her "chronic disability."

For persons with cleft palates and harelips—to illustrate from a different area—rehabilitation was not considered feasible because the disability interfered with the client's preparation for an occupation commensurate with his capabilities or with his attainment of experience necessary for entering an occupation. Many of these people were placed, without service, in jobs requiring menial labor, where they did physical work but gained no mental satisfaction. This deepened their emotional problems, and they were considered misfits in society. Now it is possible to provide these clients with prosthetic appliances which enable them to speak and with surgery which can reduce the disability to the point where one would hardly be aware that it exists. For such persons the physical restoration program has opened a new world.

60 Percent of Total

But what has all this to do with meeting the problems of those who are handicapped because of a chronic disability? A review of the bureau's case records of the 3,011 persons rehabilitated in 1953 revealed that 1,817 of them were disabled because of disease, amounting to 60

percent of the total rehabilitated. Among these 1,817 clients are cases of poliomyelitis, epilepsy, hemiplegia, paraplegia, cardiac involvement, mental illness, diabetes, tuberculosis, bronchiectasis, silicosis, hearing deficiency, Buerger's disease, cerebral palsy, and cancer. Today these people are all gainfully employed and are now "tax-paying" instead of "tax-costing" citizens.

The bureau has not provided rehabilitation services for narcotic addicts, but it has helped many disabled individuals who, because of their disability and the factors involved, have become alcoholics. The division of alcoholic studies of the Pennsylvania Department of Health is now establishing facilities throughout the State for the treatment of alcoholics, and the bureau of rehabilitation is planning to assist in the rehabilitation of those who in addition to being alcoholics also have employment handicaps.

In 1953, the State legislature appropriated more than \$2 million for the construction of a comprehensive rehabilitation center in Pennsylvania. With the completion of this facility and the expansion of the rehabilitation program through passage of new laws by Congress in 1954, the bureau's program will provide additional services for chronically disabled individuals.

Chronic Disease Factor In Public Assistance

PHR Studies of public assistance recipients in Illinois, Connecticut, New Jersey, and Wisconsin show that about one-fourth are chronic invalids. An analysis of the public assistance rolls in Pennsylvania indicates about the same proportion of chronically ill persons.

By Robert P. Wray, deputy secretary of the Pennsylvania Department of Public Assistance.

On Pennsylvania's present assistance rolls are 60,000 persons, age 65 or over, in the old-age assistance category; 16,000 persons in the blind category; 12,000 permanently and totally disabled persons in the aid-to-disabled category; 103,000 persons in the aid-to-dependent-children category, approximately 26,000 of them adults; and 42,000 persons receiving general assistance, most of whom are adults. It is observed from the description of these categories that the bulk of assistance recipients who are chronic invalids are in the old-age assistance, blind pension, and aid-to-disabled categories. Collectively these constitute the hard long-time core of the public assistance rolls.

Cause of Impairments

A study the Pennsylvania Department of Public Assistance made of the social and medical characteristics of persons receiving financial help in the aid-to-disabled category showed that three types of diseases or conditions account for nearly two-thirds of all the major impairments suffered by these recipients. Heart and circulatory diseases rank first and account for 33 percent of the major impairments for the total group. Paralyzing conditions account for 20 percent of the impairments, and arthritis and other bone diseases fall in third position with a rating of 12 percent. Respiratory diseases, mental and psychiatric disorders, and tuberculosis each accounts for 6 percent of the major impairments. Three percent of the total impairments are attributable to cancer, syphilis, ear and eye diseases, and epilepsy, respectively. Diseases of the digestive system occur in 2 percent of the recipients, and diabetes is the cause of the major impairment in 1 percent of the cases. The other 2 percent of the recipients have a variety of major impairments that are too diversified to classify.

Forty-two percent of the group studied had been impaired for 10 or more years; 20 percent, between 5 and 10 years; 27 percent, between 2 and 5 years; and in 8 percent of the instances the elapsed time since disablement was less than 2 years. The period of disablement was not reported for the remaining 3 percent.

Approximately 6 percent of the impairments

suffered by the group studied were caused by diseases or injuries resulting from employment. The incidence of such disabilities increases rapidly with age and is much higher for men than for women. Injuries not connected with employment are responsible for only 4 percent of the major impairments. Congenital conditions or injuries at birth account for approximately 5 percent of the disabilities. The great majority of disabilities are brought on by age or serious illness and for the most part are chronic or degenerative diseases. Heart and circulatory ailments are the most common. About one-third of the mental and psychiatric disorders are congenital or were caused by certain injuries, as were about one-fifth of the epileptic impairments.

Where They Live

Most of these disabled persons are living in their own homes or at the homes of relatives or friends. With considerable effort they manage to care for themselves, and many of them undergo suffering and distress because they do not have other persons to care for them.

About 5,500 recipients of assistance, most of them chronic invalids, reside in institutions. About one-half of these are in nursing or convalescent homes. About one-fifth are in commercial boarding homes for the aged and another one-fifth, in other miscellaneous homes for the aged. The remainder are blind persons living in homes maintained by county institution districts. Under Pennsylvania's public assistance laws only blind pensions can be granted to persons residing in a public institution. Most of this group of 5,500 persons are able to manage their own affairs, and guardians or trustees have been appointed for only a small fraction. All of these persons, however, need some services beyond the basic items of food, shelter, and laundry. They are predominantly an aged group. The average age is 78 years, and 7 percent are 90 years of age or more.

A comparison of the above figures with similar studies made in other States indicates that these same relationships for all disabled persons are found rather generally throughout the

country. In a booklet entitled "Care of the Long-Term Patient," the Public Health Service has reported some comprehensive statistics for 1950. The study showed that in the country as a whole there were an estimated 5,298,000 persons who had been disabled for more than 3 months. Seventy-nine percent of these were living in places outside of institutions, such as their own or other private homes, boarding houses, or hotels. Twelve percent were in mental hospitals; 7 percent were in homes or schools for the handicapped and the aged and dependent; 1 percent were in tuberculosis hospitals, and less than one-half of 1 percent were in chronic disease hospitals and correctional institutions.

Money Grants

Under Pennsylvania's public assistance program, money grants are made to persons who are found to be in financial need on the basis of schedules of assistance allowances established by the Pennsylvania Department of Public Assistance with the approval of the Pennsylvania State Board of Public Assistance. Grants are made either to the assistance recipients themselves or to a trustee or guardian.

As mentioned, persons receiving a blind pension may reside in a public institution where they receive care and attention. Other recipients may reside in various types of privately operated institutions, but the assistance allowances do not include any additional amount of money necessary to pay for institutional services.

Under Pennsylvania law, county institution districts have a responsibility for persons who are physically and mentally infirm. As a result of a divided responsibility between the department of public assistance and county institution districts for indigent persons who are physically or mentally limited, it is an understatement to say that their needs are not being adequately met. But even if legislation is enacted to fix responsibility for this group of persons, this action in no way will decrease the number of persons who are financially dependent and in need of care.

The basic problem of disabled persons, including those with chronic illnesses, should be met by providing facilities for the care, treatment, and rehabilitation of those presently afflicted with chronic illnesses and by conducting an intense program of research into the causes of chronic illness in order to reduce the incidence and improve the methods of treatment. For the long run only the latter alternative will provide a solution.

Facilities Inventory For Chronic Sickness

PHR In Pennsylvania, one of the greatest needs of patients with chronic illness is for better facilities. Pennsylvania does not have one hospital specifically designed for the care of the chronically ill. However, four projects of this type have been requested under the new Medical Facilities Survey and Construction Act of 1954.

The chronically ill patients are now being cared for in the existing 1,344 institutions supervised or licensed by the bureau of homes and hospitals of the Pennsylvania Department of Welfare. These institutions by classification are 356 hospitals (exclusive of mental); 419 licensed nursing and convalescent homes; 289 licensed boarding homes for the aged; 218 nonprofit homes; and 62 county homes. Eighty-seven of the hospitals are licensed proprietary, and the rest are incorporated nonprofit.

Pennsylvania needs 20,968 beds for chronically ill patients, or 2 beds per 1,000 population, according to the 1954 revision of the State plan required under the Hospital Survey and Construction Program. Twenty-four facilities

are now supplying 1,613 acceptable and 358 non-acceptable beds. Nursing, convalescent, and boarding homes account for approximately 10,390 of the remaining 18,997 beds.

Under Pennsylvania law every home keeping for profit one or more persons requiring care, treatment, or nursing for sickness, injury, or other disability is required to be licensed. Every home providing for profit service or domiciliary care for three or more elderly persons who are not ill or in need of nursing care must also be licensed. No person classified as a patient may be kept in a licensed boarding home for the aged.

County homes give care—some of it good and some very poor—to all types of dependent persons. Fourteen county homes have approved medical facilities. Nine counties have no county homes. The department of welfare is making determined efforts to improve the care of the residents of these homes. One of the greatest problems facing the department is to get the individual county institution district authorities to recognize their responsibility for the care of their ill dependents. This responsibility is placed on these authorities by the county institution district law, which states "dependent means an indigent person requiring care because of physical or mental infirmity." A survey completed in the spring of 1954 shows that 43 counties contribute to patient care in nonprofit hospitals.

Responsibility for supervision of nonprofit homes for the aged was placed with the Pennsylvania Department of Welfare by the 1953 session of the State legislature. Rules and regulations for this group have been completed and mailed to them.

Although the number of institutions responsible to the bureau of homes and hospitals is steadily increasing, we do not now, nor can we in the foreseeable future, have anywhere nearly enough homes for all of our needy aged and chronically ill. Therefore, the department of welfare is doing all it can through education and consultation to see that the institutions under its supervision meet State requirements and give proper care to the needy residents of the State.

By Ira J. Mills, director of the bureau of homes and hospitals of the Pennsylvania Department of Welfare.

The Local Health Laboratory

PHR Laboratory service related to health is a cooperative effort between laboratory scientists who provide factual data and qualified persons who apply the data to the individual, the group, or the community.

To provide service intelligently, the laboratory should have some knowledge of the conditions under which the specimens were collected and other pertinent facts that will direct the laboratory efforts into productive channels. It must be aware of any special problems peculiar to the specimen which might influence the scientific findings of the laboratory.

The physicians or health officers the laboratory serves should receive laboratory reports as early as possible. Every day, in fact every hour, that passes between the time the specimen is collected and the time the report is received means just that much delay in applying the scientific facts of the report to the diagnosis of the disease and its indicated treatment or in instituting the proper measures to control its spread.

In short, close liaison must be maintained between the laboratory and its patrons if the service is to be effective and efficient. Local laboratories have the advantage of prompt communications—face-to-face conferences, local telephone calls, and short-distance written communications.

The liaison is particularly important to local, county, and district health departments since scientific facts, which can be determined only in the laboratory, are frequently the basis on which health department activities rest. No health department, regardless of the size of the population it serves, can operate efficiently without prompt laboratory service, which is best furnished by a local laboratory.

By Edmund K. Kline, Dr.P.H., director of laboratories, Cattaraugus County Department of Health, Olean, N. Y.

Although for many years the larger municipal health departments have maintained laboratories to provide local service, public health authorities have been slow to recognize the need for local laboratory services for suburban and rural populations through laboratories organized as integral divisions of local health units.

Decentralization

In the field of public health, laboratory service, in general, has been supplied by State health departments on a statewide rather than a local basis. In a small State, the central laboratory can perhaps serve the entire State, but centralized service in a larger State becomes increasingly difficult because of the lack of proper and prompt communication.

Many States now have programs aimed at decentralizing laboratory services, either by establishing branches of the central State laboratory or by stimulating the formation of local laboratories.

The State branch laboratory is actually a part of the State laboratory, under direction of the State laboratory director. Its personnel are State employees, and it is financed by the State as a part of its laboratory budget. It is usually placed in a strategic communications center for the purpose of getting the maximum amount of rapid mail service from the largest possible territory.

Maryland and Alabama, for example, have branch laboratory systems covering the entire State. Maryland maintains 12 branch laboratories in addition to the central laboratory in Baltimore, and Alabama maintains 8 branch laboratories directed from the State laboratory in Montgomery. Several other States maintain a few branch laboratories at strategic points but do not have a statewide coverage. Michigan has branch laboratories in Grand Rapids and Houghton, and Pennsylvania has branches in Wilkes-Barre and Pittsburgh.

The development of decentralized local laboratories integrated into a statewide system, but maintained by local communities, is well illustrated by the experience of New York State. The basic law promoting such service, passed in 1923, permits the county governing body, the

board of supervisors, to establish local laboratories to serve a whole or a part of a county. The same law permits the establishment of municipal laboratories by the city council or the incorporation of municipal services into the county laboratory district.

These local laboratories may be operated as independent services under a county board of laboratory managers or as an integral part of a city or county health department, or the city or county may contract with a hospital to have both public health and hospital services performed in a single laboratory. They operate under the supervision of the division of laboratories and research of the New York State Health Department, which inspects them, sets standard qualifications for their directors, reviews their methods, and issues annual certificates of approval to them.

A provision in the New York State law granting State aid to the extent of 50 percent of the net cost of operating the laboratories encouraged and stimulated their establishment. As a result of these permissive laws, New York State has some 45 city and county public health laboratories, most of them operating in conjunction with hospitals. In addition, about 105 hospital and private clinical laboratories have State health department approval although they do not receive financial assistance.

California has some 43 local laboratories administered under the jurisdiction of local health officers and supervised by the State laboratory.

Scope of Service

The scope of local laboratory service depends in part on the program of the local health department and in part on other local laboratory services available. It may even include services related to clinical and hospital medicine.

Traditionally, public health laboratory services have been related to communicable disease control and sanitation. All other laboratory services related to health have been classified as clinical and usually have not been performed in a public health laboratory.

However, in recent years the concept that all disease is a problem of the community has gained considerable headway, and official health departments have expanded their activities to

embrace such programs as diabetes and cancer control, geriatrics, dental hygiene, and mental health problems—programs that go far beyond communicable or community disease.

The prevention and control of communicable disease will certainly continue to be a part of all health department activities, and all local laboratories will continue to be prepared to identify the causative organisms and the vectors of such diseases and to perform the sanitary examinations that are concerned with their spread in a community.

If the local health department operates clinics or hospitals, the local laboratory will perform the examinations that will provide diagnostic or prognostic information regarding the patients attending the clinics or served by the hospitals.

Except for the diagnostic services with relation to communicable diseases, the services required by private practitioners will usually be referred to private commercial or hospital laboratories. However, if other local facilities are not available, services in such fields as hematology and biochemistry may have to be provided by the local health laboratory.

The health laboratory should also be prepared to serve the entire community in certain specialties, such as parasitology and mycology, if these services are not available at other local laboratories.

If, as is the general pattern in New York State, the public health laboratory is also acting as a hospital laboratory, its scope of service will be all-inclusive. The only distinction between public and private service is that patients who can afford to pay are usually charged a fee for all service not directly related to the communicable diseases. Welfare patients, or those classed as medically indigent, receive all services free of charge.

Organization

In even the smallest laboratory some effort should be made to departmentalize the work even though two or more departments must be combined under a single individual. Departments of bacteriology, serology, sanitary bacteriology and chemistry, hematology, and clinical chemistry, in addition to service and cleri-

cal departments, are the essential ones. If hospital service is included, a separate department of tissue pathology is indicated. Specialties, such as parasitology, mycology, and virology, which do not furnish a volume of work sufficient to support a department, should be integrated into other departments according to the knowledge and skill of the workers in them.

Even if the laboratory staff is too small to provide one worker for each department, it is a great convenience to group the materials and supplies needed for each of the separate activities in one part of the laboratory and to attempt to arrange the flow of specimens through the laboratory as though there were separate and distinct departments.

Broad training in the laboratory sciences is indicated for the personnel in a local laboratory. Obviously, if one person has to serve in more than one department, he will have to be skilled in more than a single scientific specialty. Not many such broadly trained persons are available, but, if necessary, inservice or brief postgraduate training courses may be used to teach competent employees to function in several of the specialties.

Integration in a State System

If a comprehensive local laboratory coverage is developed and maintained, it must not be assumed that the services demanded of the State laboratory will decline. In fact, exactly the reverse is true, for in New York and California, the two States with the most comprehensive local laboratory coverage, the State health department laboratories have grown steadily year after year in response to new service demands. True, there may be a shifting away from the performance of simple routine examinations and concentration on the more specialized types of service and greater administrative and research responsibilities.

The local laboratory will be dependent upon a central State laboratory for many parts of its service program. In certain instances, it is desirable to have unexpected or unusual findings checked by some authority. For this purpose a State laboratory should offer a reference diagnostic service to review and confirm such results. The local laboratory will not be able

to employ experts in every scientific field. However, the State laboratory usually has such experts on its staff or has access to them through Federal agencies or educational institutions.

In certain technical fields it is neither desirable nor profitable for the local laboratory to carry its specimens to the final end result. For instance, the exact antigenic analysis of every *Salmonella* species isolated in a local laboratory is unnecessary. Culture of such organisms should be referred to the State laboratory for final studies.

Certain laboratory reagents can only be prepared and standardized in laboratories with access to sufficient clinical material to afford a proper evaluation. Other reagents are best prepared in large batches, each batch being carefully standardized so as to be of uniform titer and reactivity with previously used batches. The State laboratory should assume responsibility for all such reagents, either by actually preparing them or by testing commercial products and distributing them to the local laboratories.

State Responsibilities

The State laboratory should be the scientific center around which all of the laboratory work in the State is focused. It should keep abreast of new scientific and technical developments, determine their applicability within the State, and if found desirable recommend them to the local laboratories. It should also assume some administrative responsibility for the quality and uniformity of services provided by local laboratories.

Some uniformity of methods and reporting should be common to all local laboratories within a State. For instance, in reporting serologic tests for syphilis, it is confusing to have one laboratory report a result of 3+ while its neighbor reports it as positive 2 dils or 6 units. Likewise, it is not desirable to have one laboratory report on complement fixation tests alone while its neighbor reports on flocculation tests alone. Discrepancies, which will reflect on both laboratories, are bound to occur.

Either the State laboratory should prescribe and approve all methods, as does New York, or else the results of test specimens sent out by the

State laboratory should be used as criteria for assurance, that comparable work is being performed by the local laboratories.

To minimize errors in technique or deviations from the accepted methods that may lead to incorrect results, the State laboratory should submit a series of "test specimens" to local laboratories from time to time. This procedure will check the actual performance of these laboratories against each other and against suitable control laboratories.

Maryland and Massachusetts have developed extensive programs of this type. Many other States have tried limited programs, and almost every State has used test specimens for syphilis serology in programs patterned after the Federal program for evaluating State laboratories.

The struggle to insure competent personnel for all laboratory services is a continuing one. The State laboratory should assist the local laboratories to maintain a high level of competence by setting standards, both in education and experience, for all local laboratory employees, and it should insure that these standards are met.

New York approves the qualifications of local directors only. California licenses all technical

employees after examination. Connecticut requires all serologists in local laboratories to prove competence by performance tests in the State laboratory.

The California State Health Department also licenses all schools giving courses in laboratory science and issues registration certificates to all trainees in such schools. Upon completion of a prescribed training course, the State gives examinations. Those passing the test are licensed to work either in health department laboratories or in the 800 to 900 clinical laboratories licensed in the State.

The State laboratory can assist in training by encouraging personnel from local laboratories to spend training periods in the State laboratory. Refresher courses may be offered in the State laboratory or in selected training centers covering various regions of the State. Specialty experts can be sent on trips to local laboratories. Some States have made scholarships available to local laboratories for advanced study at educational centers.

Finally, the State laboratory should take active leadership in all activities of health laboratories of all kinds in order to weld them into a harmonious service system.

On the Care of Premature Infants

"Your Premature Baby," a pamphlet for parents of prematurely born babies, has been recently issued by the Children's Bureau, Department of Health, Education, and Welfare, as a supplement to the bureau's booklet on "Infant Care."

All babies weighing $5\frac{1}{2}$ pounds or less at birth are usually considered as premature.

The new leaflet tells parents what happens to their child at the hospital until the time when he is ready to be brought home and why he may need special care. It provides brief answers to the questions that parents most commonly ask, such as: Will the baby always be small and weak? Will he be "late" in developing? Will he be normal mentally? Does a 7-month premature infant have a better chance of surviving than an 8-month infant has?

Copies of the new publication may be purchased from the Superintendent of Documents, United States Government Printing Office, Washington 25, D. C., for 10 cents each.

technical publications

Management of Venereal Disease

Public Health Service Publication No. 327. Revised 1954. 14 pages.

The 1954 revision of this pamphlet briefly states the latest (as of June 1, 1954) information available on the treatment and re-treatment of venereal diseases. The pamphlet is available to physicians, nurses, students of medicine and allied professions, medical societies, and other professional groups.

The schedules for treatment of primary and secondary syphilis are based upon experience of the Venereal Disease Branch, Public Health Service. Schedules for treatment of other stages of syphilis and other venereal diseases are based upon experience of various workers and have been used satisfactorily at the Service's treatment centers.

The management of gonorrhea, nonspecific urethritis, saprophytic spirochetel balanitis, chancre, granuloma inguinale, and lymphogranuloma venereum, as well as syphilis, are outlined in the pamphlet.

Chronic Illness

Digests of Selected References, 1950-52

Public Health Service Publication No. 305 (Public Health Bibliography Series No. 1, Supplement). 1953. By Violet B. Turner. 262 pages. \$1.00

In 1951, digests of selected references on chronic disease published before 1950 were issued as Public Health Service Publication No. 10. This supplement contains digests of articles and books published during 1950-52. The digest numbers are continued from the earlier bibliography and the indexes cover both publications.

In a few instances publications issued before 1950 and early in 1953 are included. A new section on planning, design, and construction of institutions for the chronically ill, for example, was made as complete as possible by including some earlier references even though a few entries duplicated those in the first volume. Other new sections are those on coordination of facilities and services and on prevention and control. The subsection on nursing homes has been divided into three parts to facilitate its use.

Remaining sections in the bibliography are: dimensions of the problem, contributory factors, rehabilitation, non-institutional services, and institutional services.

Clinical material dealing with specific medical diagnosis or treatment of chronic disease has been excluded in both volumes.

Communicable Disease Center Activities, 1952-53

Public Health Service Publication No. 391. 1954. 31 pages; illustrated.

Intended as an aid to State, local, and other health agencies in planning their programs, this report summarizes the major activities of the Communicable Disease Center, Bureau of State Services, Public Health Service, during the fiscal year 1953.

It treats in general terms, rather than precise grouping, the scope, nature, and interrelationships of activities as conducted in different areas of the public health field by the CDC staff. The current structure of the center is shown in a flow chart; its professional personnel are described, and field installations are listed.

The report discusses projects pertaining to established procedures and practices, such as administration and management, epidemic intelligence service and disaster aid,

laboratory training, disease control operations and demonstrations, control of arthropod vectors and animal reservoirs of disease, and training programs for field work and for aids.

The section entitled "Activities Directed Toward Specific Diseases" discusses the CDC activity in relation to such individual diseases as anthrax, diarrheal diseases, encephalitis, leprosy, malaria, pinworms, poliomyelitis, rabies, trichinosis, and many others.

Report of Local Public Health Resources, 1952

Public Health Publication No. 398. 1954. By Clifford H. Grace, Josephine R. Campbell, and Kathryn Connor. 85 pages; tables.

This annual report of personnel, facilities, and services in local areas is the sixth since 1946 in a series of analyses based on data submitted to the Public Health Service by full-time local health organizations. Data for 1948 is unpublished.

Those units reporting as of December 31, 1952, (excluding Alaska, Hawaii, Puerto Rico, and the Virgin Islands) number 1,313 organizations and include 2,207 counties and 215 independent city health departments serving more than 88 percent of the population of the United States. Approximately 50 units did not report.

The current analysis in addition to the extent of coverage is presented in these categories: personnel engaged; selected public health services and clinical facilities; selected community sanitation facilities and services; and per capita expenditures for public health and per capita income of areas served.

The number of personnel employed full-time increased over the previous year. Public health nurses continued to be the most acute staffing deficiency in the majority of health units, followed by sanitation personnel, physicians, and clerks.

The selection of services and clinical facilities for inclusion in the report was made on the basis of significance to program divisions of the

technical publications

Public Health Service and the Children's Bureau. Provision of chest X-ray for tuberculosis case finding ranked first among services reported. Topical fluoride application and diabetic group instruction were the two reportable services least frequently included in health programs.

In the selected community sanitation facilities and services category, there was slight difference between the 1952 information and that submitted for 1951.

For the first time this 1952 report carries information on the expenditures for public health services by units and the per capita income for each jurisdiction. The majority of the single county units and local health districts spent between \$0.50 and \$1.00 per capita; the largest proportion of city health departments, \$1.00 and \$1.50. No expenditure data were available for 9 percent of the reporting units.

Pulmonary Fibrosis in Soft Coal Miners

An annotated bibliography on the entity recently described as soft coal pneumoconiosis

Public Health Service Publication No. 352, Public Health Bibliography Series No. 11. By H. N. Doyle and T. H. Noehren. 59 pages. 25 cents.

This bibliography contains abstracts of publications presenting information on a form of respiratory disability among soft coal miners believed to be unrelated to and different from silicosis. The disability is associated with prolonged inhalation of excessive amounts of coal dust. The incidence of the condition is particularly high in south Wales, and Great Britain has been making long-range comprehensive studies of the disease, which is gaining in medical significance. Various groups in this country are

finding these studies of particular interest.

The foreword of the bibliography describes the symptoms of the pulmonary ailment and explains the identification and nomenclature problems met in assembling the material for this publication. It points out that the compilers have chosen papers presenting a cross section of views on the subject and historical reviews, using as much as possible in their abstracting the language of the original authors.

The abstracts are chronologically arranged—the first, a paper published in 1834.

Directory of State and Territorial Health Authorities, 1954

Public Health Service Publication No. 75. Revised 1954. 73 pages. 30 cents.

The 1954 revision of this directory was compiled from information reported to the Public Health Service as of May 1954 by State and Territorial health departments and by other State agencies participating in grant programs administered by the Public Health Service. Also included are agencies officially designated for the administration of the Water Pollution Control Act and State agencies other than health departments administering crippled children's services.

The listing of health department personnel is designed to reflect the organizational structure of State health departments and to delineate placement of responsibility for the major health functions. The principal organizational units and subordinate components are arranged alphabetically, according to the current departmental organization. The name of each health official appears opposite the unit which he

directs. If the name of the health unit is not self-explanatory, its major functions are noted.

The title and location of each State health department and the name of the health officer in charge is in a section preceding the organizational listing of officials for the individual States. The same information is shown for other State agencies designated to administer any pertinent program, such as mental hygiene.

Personnel of the Public Health Service in charge of functions closely associated with State health departments are listed in the appendix.

Refuse Collection and Disposal

A Bibliography—1951–1953

Public Health Service Publication No. 402. Public Health Bibliography Series No. 4 (Supplement A). 1954. 39 pages.

The first volume of this bibliography, Public Health Service Publication No. 91, listed items which appeared during 1941 and 1950. The present supplement covers the years 1951–53.

The organization of the listings is substantially the same as in the first volume. The five main divisions of the bibliography are regulations, finances, storage, collection, and disposal. The sections on collection and disposal are subdivided further as in the earlier book.

This bibliography is intended as an aid in the exchange of information in research and operational phases of refuse-sanitation activities.

Home Care of the Sick

Public Health Service Publication No. 70, Health Information Series No. 21. Revised 1954. 2-fold leaflet. \$2.50 per 100.

This leaflet contains general information on taking care of sick persons at home. It describes how to select a bed and other sick room

technical publications

equipment and gives similar patient-care instructions. The publication also outlines ways in which the attendant can be of help to the physician and suggests organizations and individuals who can give instructions in nursing care.

Ringworm

Public Health Service Publication No. 46, Health Information Series No. 6, Revised 1954. 1-fold leaflet, \$2.00 per 100.

Ringworm is the common name for skin disease caused by a fungus growth. This leaflet describes four varieties and their effect upon the body. The most common is ringworm of the feet known as athlete's foot; the others are ringworm of the scalp, of the body, and of the nail.

The pamphlet tells of the symptoms of each, explains the danger of contagion, and suggests preventive measures. It advises seeking prompt medical attention to obtain proper treatment in each case.

Proceedings of the Third Research Conference on Psychosurgery: Evaluation of Psychosurgery

Public Health Service Publication No. 221, 1954. 173 pages; illustrated. \$1.00.

The proceedings of the Third Research Conference of Psychosurgery held in New York City in 1951 under the auspices of the National Institute of Mental Health, Public Health Service, are presented in this publication. Most of the participants had also attended the two previous conferences: the first, held in 1949, on the criteria for selection of patients for psychosurgery; the second, in 1950, on the determination and measurement of the effects of psychosurgery.

The 1951 conference devoted its attention to a general evaluation of psychosurgery—its indications, methods, and results. The theme of the conference is developed by the speakers as they give their evaluation of psychosurgery in relation to drive, social service, reaction to painful stimuli, treatment of intractable pain, psychoneurosis, sex variants, psychopathic personality, and organic cases with emotional manifestations.

The publication also includes the report on techniques of psychosurgery given by the Committee on Surgery, a summary of the findings of the three conferences, and appendices.

Pinworms

Public Health Service Publication No. 108 (Health Information Series No. 51), Revised 1954. 1-fold leaflet, 5 cents, \$2.00 per 100.

Pinworms are discussed from the viewpoint of their effect on persons, especially children in this recently revised leaflet. Symptoms and diagnosis of pinworm infection are described. Suggestions are offered for the control of pinworms and their eggs to prevent spread of infection within a household. Treatment by a physician is recommended for infected persons.

Hospital Services—Pharmacy

Prepared by the Division of Hospital Facilities, Public Health Service, 1954. 42 pages; illustrated.

Suggested plans, equipment, supply lists, minimum standard, and organization for hospital pharmacies are presented as an integral part of the Public Health Service activities relating to the Hospital Survey and Construction Program.

Directed to architects, hospital administrators, pharmacists, and others concerned in hospital planning, this pamphlet is designed to help them understand the functions, layout, and equipment of hospital pharmacies.

The booklet is a compilation of articles prepared by the Division of Hospital Facilities which have appeared in other journals. The five sections of the booklet include suggested plans for hospital pharmacies; suggested equipment lists for hospital pharmacies; pharmacy supplies and pharmacological index; minimum standard for pharmacies in hospitals; and a discussion of the value of a hospital pharmacist.

Home Sanitation

Public Health Service Publication No. 234, Health Information Series No. 56, 2-fold leaflet, \$2.50 per 100.

Home sanitation facts, important in the control of communicable diseases, are pointed out in this leaflet. It describes the precautions that should be taken to safeguard the water supply and gives advice on sewage and refuse disposal. Outlined are the best methods of combating flies and other insects and rats. It also gives information on proper light and ventilation, heating, plumbing, refrigeration, and accident prevention in the home.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Utilization of Local Health Centers in 25 North Carolina Counties.

By A. L. CHAPMAN, M.D., M.P.H., J. W. R. NORTON, M.D., M.P.H.,
and EDWARD E. SPRINGBORN, B.C.S.

HISTORICALLY, many local health departments have been poorly housed, frequently in the basements of county courthouses or city halls.

During World War II, under the provisions of the Lanham Act, modern health centers were built in various parts of the country near important military installations or defense plants. The passage of the Hospital Survey and Construction Act in 1946 made it possible for State hospital authorities to include participation in the construction of local health centers in their overall State hospital plan. Some States, among them North Carolina, have taken advantage of this opportunity and have participated in the construction of a significant number of modern local health centers. These centers have increased the stature of local health departments and have greatly improved the effectiveness and morale of the public health workers who use them.

Great care has been taken in planning and constructing these health centers. Their

Dr. Chapman is regional medical director, Region II, Department of Health, Education, and Welfare, New York City; Mr. Springborn is a public health representative, Region III, Washington, D. C.; Dr. Norton is secretary-treasurer and State health officer, North Carolina State Board of Health, Raleigh, N. C.

architectural and engineering features, with minor exceptions, reflect the high quality of architectural and engineering skills that contributed to their design and construction. It always is more difficult to modernize traditional public health programs than it is to adopt modern architectural designs in the construction of new health centers.

With this thought in mind, the authors queried a group of local health officers in North Carolina concerning certain phases of the programs that were being conducted in their local health centers. The staffs of the North Carolina State Board of Health and of the local health departments concerned cooperated in the study.

The sample selected consisted of 25 counties in which there had been erected local health centers with the aid of Federal, State, and local funds. These counties were:

Beaufort	Harnett	Rutherford
Burke	Hertford	Sampson
Caldwell	Martin	Scotland
Caswell	Moore	Stanly
Currituck	Northampton	Tyrrell
Dare	Person	Warren
Franklin	Robeson	Wilson
Edgecombe	Rockingham	
Halifax	Rowan	

These 25 county health departments comprise slightly more than one-third of the local health departments in the State. The list does not include the largest or the smallest health depart-

ments, nor does it constitute a cross section of all North Carolina county health departments.

The director of local health services of the North Carolina State Board of Health distributed a questionnaire to each of the 21 full-time local health officers and the 1 part-time health officer participating in the study. The questionnaire requested information about the community and specific data concerning clinic services, staff, and space utilization.

After ample time had passed to permit the local health officers to complete the questionnaire, a member of the staff of the Public Health Service regional office (Region III, Department of Health, Education, and Welfare) visited each of the 25 local health departments to interpret the meaning of any questions which were not clear. He also talked to various members of the local health department staffs to obtain their impression of their health center.

Study Counties

From the data obtained it was possible to develop a composite picture of the 25 counties, their health centers, their services, their staffing patterns, and their problems. The "composite" county has a population of 38,137 persons, of whom 65 percent are white and 35 percent, non-white. Twenty-one percent of the population are urban, 79 percent, rural. The birth rate in these 25 counties was more than 3 times the death rate. In 1953 there were 1,071 births compared to 323 deaths. The annual per capita income was \$830. The annual per capita expenditure for public health was \$1.00. Slightly more than 0.1 percent of the annual per capita income was budgeted for public health purposes.

There were 18 practicing physicians and 7 dentists to serve the 38,137 persons in the composite county, a ratio of 1 physician to 2,119 persons and 1 dentist to 5,448 persons. The bed population ratio for the composite county was 2.66 beds per 1,000 population. All were general hospital beds. The utilization of beds was good, the average daily census being 72.5 percent of the total number of beds available.

Although the outpatient services offered by the 34 hospitals serving the 25 counties did not compare in quality or quantity to the services

available in most metropolitan areas, they exceeded in quantity the outpatient services usually provided in predominantly rural areas. Six of the 34 hospitals maintained outpatient services. These 6 hospitals served 24 percent of the total population of the 25 counties. The remaining 28 hospitals offered only inpatient and emergency services.

The average size of the 25 health centers was 3,110 square feet. The average cost, including equipment, was \$51,900, or 15.20 per square foot. The per capita cost of the health centers, including equipment was \$1.36.

12th grade.....	1	45	. 03
Total.....	153	130, 012	-----

The staffs of the local health departments studied, although not up to the quantitative standards recommended by the American Public Health Association, were not out of line with the staffing patterns of other rural health departments. All but 1 of the 25 county health departments had a full-time health officer. The population ratios for other staff members were: public health nurses, 1/10,834; sanitarians, 1/27,241; and clerks, 1/25,090.

The 10 leading causes of death in North Carolina—heart disease, brain hemorrhage, cancer, accidents, certain diseases of early infancy, in-

fluenza and pneumonia, tuberculosis, nephritis, congenital malformations, and general arteriosclerosis—followed the pattern that has been developing throughout the United States for decades.

The types of clinics held in the 25 counties, the number of patient visits to the clinics, and the number of health centers conducting each type of clinic are shown in the accompanying table.

The average amount of space provided for each public health nurse was 84 square feet. The space allotted to sanitarians averaged slightly more—104 square feet. The public health nurses and sanitarians, it was estimated, spent an average of 1½ hours in the office each working day.

In the health centers, 4.8 percent of the space was occupied by laboratories that were maintained in 22 of the 25 health centers. The average number of square feet of laboratory space was 168. Only 1 of the 25 local health departments employed a full-time laboratory technician at the time of the study.

Each of the 25 health centers had waiting rooms that were used as meeting places. The average seating capacity was 55. All of the health officers reported that the waiting rooms were used in the evenings by various community groups. Typical of these groups were local boards of health, voluntary health associations, local Red Cross chapters, PTA groups, medical societies, boards of education, and farm groups.

Nine health centers had separate conference rooms averaging 170 square feet in size, with an average seating capacity of 13. Only 5 health centers had a library, but all made some provision for placing professional books and journals at the disposal of their staffs.

Health Services

Certain characteristics of the health services provided in these 25 rural health centers lend themselves well to discussion; some present basic challenges to present concepts of providing rural public health service.

Increasing Population

The marked excess of births over deaths represents, in part at least, the success of past

and present public health services, improvements in medical and hospital care, and a better economy. It also portrays rather dramatically the current upsurge in our total population. This increase in population will continue to require an expansion in local public health services and an increase in the number of practicing private physicians.

Financial Support

The fact that little more than 0.1 percent of the per capita income of the population of these 25 counties is budgeted for local public health services should cause us to raise our professional eyebrows. Is this relatively small financial contribution for public health services commensurate with the public health needs of these rural people? Are we failing to dramatize to the taxpayer the value of and need for health services that still are not being provided? Or is it that we are failing to offer to people the types of health services they want and are willing to pay for?

Physicians and Dentists

The physician/population ratio of 1 physician to 2,119 persons, although not meeting the recommended physician/population ratio, is not atypical of most rural communities. It does bring out the fact that if the degenerative and malignant diseases—those causing long-term illnesses—continue to increase in our aging population, the “physician hunger” of rural populations will tend to increase rather than to decrease. Some alleviation of this situation might be obtained rather quickly by the wider use of paramedical personnel to extend the services of those practicing physicians who are now available.

The dentist/population ratio of 1 dentist to 5,448 persons represents a longtime and widespread problem throughout the United States. The only optimistic factor in this picture is the growing practice of fluoridating public water supplies and the topical application of fluorides to the teeth of children who do not have access to a fluoridated water supply. A 60-percent reduction in dental caries among a large segment of the child population would permit the present number of dentists to engage in more

preventive dentistry, for which they now have little time.

Hospital Beds

The hospital bed/population ratio of 1 bed per 2.66 persons is partly the result of the State and federally aided program which assists communities to build new hospitals and to expand existing ones. The average daily census of 72.5 percent indicates that the bed supply is being well used. No beds for the chronically ill were reported in these 25 counties. Although the population approached 1 million people, there were no diagnostic centers listed as such in the 25 counties.

Outpatient Services

The availability of outpatient services to 21 percent of the population in the study area is noteworthy because it far exceeds the availability of such services in many rural areas in other States.

The fact that outpatient services are available to 85 percent of the residents of large metropolitan areas and to only a small percentage of rural residents should concern all rural health officers. Are these outpatient services merely a metropolitan luxury or is there a genuine but unmet need for them in rural areas? Is the existence of ample outpatient services in metropolitan areas merely coincidental with the existence in such areas of more and larger hospitals? Can methods be developed whereby outpatient services can be provided economically to rural residents who need them and can qualify for them? Answers to these and to other similar questions must be found if we are to develop a comprehensive program for detecting the chronic diseases in their early stages and minimizing their complications.

Health Center Cost

The per capita cost of the 25 health centers of \$1.36 was remarkably low for postwar construction. In North Carolina an upper limit has been placed on the size of all State-aided health centers, with graduated ceilings within certain population ranges. This action was deemed necessary to conserve the limited Federal and State funds available for construction of health centers in the State. It did have the

desirable effect of channeling a larger percentage of available funds into rural areas that were economically less well off than metropolitan areas. The arbitrary limitation on the size of health centers, however, had a tendency to keep the per capita cost low. Other communities intending to use the per capita cost of \$1.36 as a guide should take this factor into account. If there had been no ceiling on the size of the health centers, some undoubtedly would have been larger, which would have increased the per capita cost.

Staff/Population Ratios

All but one of the 25 rural counties had a full-time health officer. This excellent coverage is typical of North Carolina, where local public health salaries are more realistic than those of many other States. It also reflects the policy of the State health department of placing the primary responsibility for local health protection on local health departments.

The ratio of 1 public health nurse to 10,831 persons, although short of national standards, is not low in comparison with other rural areas throughout the United States.

It does highlight the difficulty that will be encountered if local public health nurses are asked to provide bedside nursing services to the chronically ill. The public health nurses in these 25 counties are hard pressed now to maintain their daily work schedules. If bedside nursing is added to their many responsibilities, the need for additional nurses, as well as for more training for the nurses now on duty, will become demanding.

Leading Causes of Death

The tabulation of the leading causes of death in North Carolina highlights the fact that undue emphasis may have been placed on the control of the infectious diseases after they had passed their peak incidence. It must be recognized, however, that maintaining the status quo will require the continuing expenditure of a significant amount of time and money. The cardiovascular diseases, cancer, brain hemorrhage, and accidents, which kill more than 75 percent of the persons who die each year, have not yet begun to be the subject of serious control efforts by the 25 local health departments

studied, although there are a few clinics for cancer, heart disease, and diabetes.

Clinic Services

An analysis of the table in which the various clinic services are enumerated (page 102) shows that the five types of clinics that were conducted most frequently by county health departments—immunization, food handlers, tuberculosis, venereal disease, and maternal and child health—accounted for 112,361 of the total 130,012 patient visits, or 86.4 percent of the total. Only the tuberculosis clinics are aimed primarily at the control of diseases which are in the list of the 10 most important causes of death. Only one of the local health departments conducts a cardiac clinic. In 1953, this clinic reported 48 patient visits. Another health department conducted a diabetes clinic and maintained supervision of some 600 patients with diabetes, at the request of local private practicing physicians. Two health departments conducted cancer clinics.

Space Utilization

The amount of space allotted to public health nurses and sanitarians, who, by their own estimate, spend an average of 1½ hours a day in the health center, gives food for thought. There is a definite trend toward group meetings and group education, as exemplified by weight control classes, patient education classes, and classes for expectant mothers (and even for expectant fathers). As long-term illnesses with their many complications gain in emphasis over acute infectious diseases, the multiplication of the duties of public health workers will demand more efficient methods of serving the public.

One way to permit scarce public health personnel to serve larger population groups is to bring people to health centers for group instruction rather than to send public health workers out to visit individuals in their homes. An example of this technique is the way practicing physicians have conditioned expectant mothers to go to hospitals for their deliveries rather than to have physicians waste precious time going to the home and waiting there for the infant to arrive. If this trend results in a need for more group instruction in health centers, additional

room will be needed in which these groups can meet.

One way to provide for additional space needs in health centers is to plan and construct them in such a way that extensions may be added with a minimum of alterations. Another possible alternative is to design the office space for public health nurses, sanitarians, and other field workers in such a way that it may be used for purposes of group instruction when it is not in use as office space. This latter alternative will require some pioneering on the part of health officers, architects, and engineers, but could well result in the more efficient utilization of health center space without imposing any real hardship on public health workers.

Laboratories

Although 22 of the 25 health centers had laboratories, only 1 of the 25 health departments employed a full-time laboratory technician. Throughout the country there is a growing awareness of the need for diagnostic centers that can serve the needs of rural physicians. When laboratory services are not readily available, physicians often must rely on their clinical judgment to make difficult diagnoses or they must resort to costly and time-consuming expedients to have laboratory work done for their patients at some distant laboratory or medical center. As soon as public health and medical leaders in local communities are convinced of the need for adequate local laboratory services, local laboratories, now inactive, may be activated and communities without laboratories may decide to obtain them. The lack of outpatient hospital services in these areas emphasizes the urgent need for the development of these assisting laboratory services.

Research workers each year are developing new tests for the chronic degenerative and malignant diseases. These tests can be of great help to rural physicians in establishing the early diagnosis of many diseases that are characterized by long periods of latency. They can help physicians to diagnose such diseases as cancer, diabetes, blood dyscrasias, nephroses, and even rheumatoid arthritis, earlier and with greater accuracy. Certainly, the patient will benefit from such early diagnoses. It would seem logi-

cal, then, to look for the better staffing of local health center laboratories with well-trained technicians, who are masters of a wide variety of laboratory tests and are capable of operating the many laboratory instruments that are being made available for disease detection.

Meeting Space

All of the health centers were provided with waiting rooms that can be used by community groups during the evening hours. This tendency to encourage community groups to use local health centers has proved to be an excellent way for health departments to provide a wider type of service and thereby earn community support for their programs. When local health departments resided in courthouse basements or attics, it was the rare individual indeed who knew where his local health department was located, the name of the local health officer, or what public health workers did to earn their money.

Construction Pointers

When the Public Health Service regional representative visited each health center, he chatted with the health officer and with other members of the staff about the general "usability" of the health center and whether or not there were features about it that they would like to see changed. The uniform reply began with an expression of appreciation that they had gotten out of their antiquated quarters and into a modern health center in which they could work more efficiently and in which they could take pride. When pressed for their reaction to the design of their own health center, there were a few items they would like to see changed.

Eight health officers stated that storage space was inadequate. Eight mentioned that their health centers were not soundproof; in fact, privacy was almost completely lacking; voices carried clearly throughout the building and interfered with the conduct of interviews, conferences, and clinics. Seven said the heating system was not efficient; the ducts were placed at ceiling level, with the result that the temperature at floor level was too low. Radiant heating was not favored for southern climates. Six

suggested that cement blocks, spray painted, plus waterproofing with a silicone type of spray would be just as attractive as plastered walls and the cost of maintenance would be lower. Five claimed that flat roofs often leaked and tended to intensify the summer heat. Air conditioning, or at least better insulation, was strongly recommended.

Other less repetitive suggestions included the separation of one of the three clinic rooms from the other two rooms with a solid wall; not pouring concrete floors over plumbing installations; and not having rest rooms open directly into waiting rooms.

Summary and Conclusions

By means of a questionnaire, supplemented by a personal visit, 25 local health officers and their staffs in North Carolina were queried about their health centers, their health services, and certain of their public health problems. The health workers uniformly expressed their appreciation for the benefits derived from being located in a modern health center.

The excellent programs conducted in these health centers were found to be oriented primarily to the control of the acute infectious diseases and to the solution of maternal and child health problems. A start is now being made on programs designed to control the chronic non-infectious diseases and the accidents that are becoming the major causes of death in North Carolina.

The fact that only one full-time laboratory technician was employed by a local health department in the entire area, comprising 25 counties with a population of 953,425, is evidence of the sparsity of laboratory diagnostic services in these rural counties, which are deficient in hospital outpatient services.

This study suggests that, now that local health departments are being "disinterred" from their basement hideaways, continuing attention should be given to the planning and evaluation of the local health services provided in health centers and to their reorientation to current public health problems.

Infantile diarrhea is a ubiquitous disease which has a high mortality rate, especially when it is unrecognized or treatment is delayed. The disease occurs not only as epidemics in nurseries but also as sporadic cases in the population.

A New Serotype of *Escherichia Coli* Associated With Infantile Diarrhea

By W. H. EWING, Ph.D., K. E. TANNER, B.S., and H. W. TATUM

A HITHERTO undescribed *Escherichia coli* serotype (O127:B8) associated with infantile diarrhea has been isolated from 121 stool cultures from 76 patients in 3 separate epidemics in Philadelphia, Pa., Cincinnati, Ohio, and Kamloops, B. C., and from cultures from sporadic cases of the disease in Mexico City. The results of bacteriological and serologic studies of these cultures and of related *E. coli* serotypes are reported.

For more than 40 years various investigators have studied *E. coli* cultures isolated from infantile gastroenteritis patients in which no recognized pathogens, such as members of the *Salmonella* or *Shigella* groups, were found. Results of earlier investigations (for references, see 14, 17, 1) were inconclusive because only biochemical methods were used in attempts to differentiate between *E. coli* cultures isolated from infants with diarrhea and cultures from normal infants. By themselves, biochemical

reactions proved inadequate for this purpose since, as is now known, different *E. coli* serotypes often give identical biochemical reactions. However, the extensive investigations of Kauffmann and his associates (15) established methods for definitive serologic typing of *E. coli* cultures and an antigenic schema in which the micro-organisms were classified.

Bray (2) and Bray and Beavan (3) apparently were the first to emphasize the association of a particular *E. coli* serotype with outbreaks of infantile diarrhea. The same type, now labeled O111:B4 (14), was isolated from 42 of 44 patients who had "infantile summer diarrhea." Independently, Varela and associates (25) in Mexico City isolated a bacterium which they named *Escherichia coli-gomez* from an infant who died of diarrhea. Later they isolated the same serotype from other patients. Varela found that the somatic antigens of *E. coli-gomez* were identical with those of *Salmonella adelaide* (O antigen 35) and he was able to employ *Salmonella* O35 antiserum in the identification of this particular *E. coli* serotype. Further studies on the antigenic relationship of *S. adelaide* and *E. coli-gomez*, as well as proof of the identity of the latter micro-organism and *E. coli* O111:B4, were given by Olarte and

Dr. Ewing is in charge of, and Mrs. Tanner and Mr. Tatum are bacteriologists in, the Shigella Typing Laboratory, Communicable Disease Center, Public Health Service, Chamblee, Ga.

Varela (18). Confirmatory investigations were made by Kauffmann (16) and in this laboratory (unpublished data).

The second *E. coli* serotype which has assumed importance because of its association with epidemic infantile diarrhea was described by Giles and his co-workers (7). Kauffmann and Dupont (14) found that the β serotype of Giles and associates (7) belonged to *E. coli* O group 55 and contained a new B antigen, B5. Smith (21) gave detailed descriptions of the α (O111:B4) and β (O55:B5) serotypes. Since 1915, cultures of *E. coli* O111:B4 and O55:B5 have been isolated during epidemics and from sporadic cases of infantile diarrhea in nearly all parts of the world.

Pertinent data regarding the two aforementioned serotypes are summarized in table 1. Also listed in the table are additional serotypes that were described in association with outbreaks of infantile diarrhea. As might be expected, epidemics have been reported in which *E. coli* serotypes O111:B4 and O55:B5 were not found and, in the examination of the *E. coli* flora from patients in such outbreaks, other serotypes common to the cases were reported. *E. coli* serotypes, other than those listed in table 1, also have been reported from outbreaks of infantile gastroenteritis, but further studies of their role in the disease are required. Cultures

of *E. coli* O124 have been isolated repeatedly from individual patients and from outbreaks of gastroenteritis and acute diarrhea in both children and adults (11). For additional information on the subject of *E. coli* serotypes associated with infantile diarrhea, readers are referred to the bibliographies of the papers cited above and reference 8. Persons interested in methods for isolation and preliminary identification of *E. coli* serotypes associated with infantile diarrhea are referred to Ewing and Edwards (13).

The cultures of the new *E. coli* serotype were received from several sources. During 1951 and 1952, 12 cultures from 3 sporadic cases in Mexico City were received from Jorge Olarte of the Hospital Infantil. These strains were studied in connection with a cooperative study of *E. coli* serotypes in sporadic cases of infantile gastroenteritis by Olarte and Ewing (unpublished data). In December 1953, 39 cultures from 9 patients in an epidemic in Philadelphia were sent by Dr. George M. Eisenberg to Dr. Edwin Neter, Buffalo, N. Y., who forwarded them to this laboratory, and 2 cultures from 2 patients were received from Dr. Merlin Cooper, Cincinnati, Ohio. During the first 4 months of 1954 Dr. Eisenberg sent 23 cultures from 17 additional patients and Dr. Cooper sent 40 cultures taken from 40 other patients during the

Table 1. Previously described *Escherichia coli* serotypes associated with infantile diarrhea

Table 2. Biochemical reactions of *Escherichia coli* O127:B8 and related serotypes

Serotype	H antigens	Number of cultures examined	Glucose, lactose, mannitol	Adonitol, inositol	Sucrose	Salicin	Sorbitol	Indol MR	VP, citrate H ₂ S	Motility
O127:B8 (4932-53, etc.)	(-)-----	107	AG	(-)	A, Ag (A)	(-)	¹ (-)	² (+)	(-)	(-)
O86:B7 (E990, etc.)	-, 8, 9, 10, or 11	13	AG	³ (-)	V	V	⁴ AG	(+)	(-)	(+/-)
O127a, 127b:B10 (2160-53, etc.)	4-----	9	AG	(-)	AG	AG	AG	(+)	(-)	(+)
O86a, 86b:B9 (5017-53)	Undescribed ⁵	1	AG	(-)	(-)	AG	AG	(+)	(-)	(+)
O90-----	(-)-----	1	AG	³ (-)	(-)	AG	AG	(+)	(-)	(-)

NOTE: AG, acid and gas production within 24 hours. A, acid only. (A) acid production delayed 48 hours or longer. V, variable, some strains positive, some negative.

-, test negative; +, test positive.

¹ 10 cultures produced acid from sorbitol after prolonged incubation (30 days).

² Indol production was weak in most strains; 72 or more hours' incubation was required.

³ 2 cultures produced acid from adonitol. The O90 culture also fermented adonitol.

⁴ 1 culture failed to ferment sorbitol.

⁵ This serotype possessed an H antigen that differed from any known *E. coli* H antigen.

same outbreak. In February and April 1954, five cultures were received from Dr. E. T. Bynoe of the Laboratory of Hygiene, Ottawa, Canada. Dr. Bynoe had received the cultures from Dr. C. E. Dolman, Vancouver, B. C., who had received them from Dr. F. P. Sparks, pathologist at the Royal Island Hospital, Kamloops, B. C., where they had been isolated from 5 patients in an epidemic of 17 cases of acute gastroenteritis in infants during September 1953. In this epidemic 8 babies were seriously ill and the remainder were moderately ill, but there were no fatalities. The cases in the Philadelphia and Cincinnati outbreaks were reported to be relatively severe—3 deaths occurred in the Philadelphia epidemic and 2 deaths in the Cincinnati outbreak.

We have been informed by the above-mentioned individuals that *E. coli* serotype O127:B8 predominated in the stools during the acute stage of illness and that members of the *Salmonella* and *Shigella* groups were looked for but were not present. In some instances, serotype O127:B8 was the only coliform bacterium in the stool cultures. Cultures of this serotype were not recovered from well babies during any of the outbreaks and, to date, none has been received in this laboratory from sources other than diarrheal patients.

We understand that further data on the clinical

aspects of infantile diarrhea, the extent and nature of the outbreaks, and other details concerning the epidemics in Philadelphia and Cincinnati will be published by Eisenberg and Cooper in separate reports. The details of the epidemic in British Columbia probably will be published by the investigators of the outbreak.

The other two *E. coli* serotypes described for the first time in this paper are O86a, 86b:B9, and O127a, 127b:B10:H4. Only one strain (5017-53) of O86a, 86b:B9 was available for study. This was isolated from a normal individual who was a member of the staff of a Philadelphia hospital. Nine cultures (2160-53 and so on) of the other serotype (O127a, 127b:B10) were recovered during a survey from stools of pediatric patients who did not have diarrheal disease.

Included in these studies were several strains of the previously described serotype O86:B7, which had been isolated recently from the stools of infants who had diarrhea. The cultures were forwarded to this laboratory for typing. The type strain for this serotype was received in 1950 from Dr. Joan Taylor (4, 24).

Biochemical Reactions

¹ Agglutination titers are expressed as the reciprocal of the highest dilution that gave strong agglutination.

cultures are listed in table 2. The reactions of the 121 strains of serotype O127:B8—which were remarkably uniform when the geographic locations of the sources were considered—were as follows: Glucose, lactose, and mannitol were fermented with gas production within 24 hours' incubation by all cultures. All cultures fermented sucrose, but a few strains required 48 hours' incubation for the reaction to appear, and some strains did not produce gas from this substrate. Salicin, adonitol, and inositol were not attacked during 30 days' incubation. The majority of strains did not ferment sorbitol within 30 days, but 10 cultures produced acid from this carbohydrate after 30 days' incubation. Hydrogen sulfide was not detected in triple sugar iron agar, acetylmethylcarbinol was not produced, and urea was not hydrolyzed. All strains failed to grow on Simmons' citrate agar, and all were nonmotile. The methyl red test was positive. All cultures produced indole but required 72 hours' incubation or

longer to produce detectable amounts of indole from 2 percent Bacto peptone water (Kovac's reagent).

Serologic Studies

The methods used for serologic studies and for anti-serum production were similar to those previously reported (9, 10, 12) and were based upon methods advocated by Kauffmann (15).

Relationships of the O Antigens

Heated broth antigens of culture 4932-53 and other strains of the new serotype referred to as O127:B8 were tested in antisera for all of the 126 known *E. coli* O antigen groups in dilution of 1:100. Positive agglutination reactions were obtained in antisera for O groups 86 and 90; all other tests were negative. Upon titration of O antigen suspensions in these two O antisera there was some variation in the titers to which the strains were agglutinated. The

Table 4. The interrelationship of the O antigens of *Escherichia coli* cultures of O groups 86, 90, and 127

O antigen suspensions (100° C., 1 hour)	<i>E. coli</i> O antisera (unabsorbed)				
	86a (E990)	90	127a (4932-53)	127a, 127b (2160-53)	86a, 86b (5017-53)
86a (E990)-----	5, 120	640	0	5, 120	5, 120
86a, 86b (5017-53)-----	20, 480	640	0	10, 240	20, 480
90-----	2, 560	5, 120	1, 280	5, 120	160
127a (4932-53)-----	1, 280	640	20, 480	5, 120	0
127a, 127b (2160-53)-----	10, 240	1, 280	10, 210	20, 480	640

average titer was 1:1,280 in O86 antiserum and 1:640 in O90 antiserum (tables 3 and 4). When heated broth antigens prepared with cultures of *E. coli* O groups 86 and 90 were tested in O antisera prepared with culture 4932-53 and identical strains, O group 86 cultures failed to react, whereas the antigens for O group 90 were agglutinated in dilutions of 1:640 to 1:1,280 (tables 3 and 4). The results of reciprocal agglutinin absorption tests with these O antisera (table 3) indicated that the O antigens of serotype O127:B8 cultures were related unilaterally to those of O group 86; whereas the relationship to O group 90 was bilateral or reciprocal. However, since the O antigens of serotype O127:B8 strains were not identical with those of *E. coli* O group 90, it was decided to assign these cultures to a new *E. coli* O antigen group, namely, O127. This decision was made after consultation with Kauffmann and Ørskov of the International Salmonella and Escherichia Center, Copenhagen, Denmark.

During the study of the O antigens of cultures of *E. coli* O127:B8, a number of other cultures related to *E. coli* O groups 86 and 90 were reinvestigated. The results of agglutination tests in unabsorbed O antisera (table 4) indicated the interrelationship of this group of cultures. Reciprocal agglutinin absorption tests indicated that the O antigens of cultures 2160-53, 2210-53, and others like these, were identical. Similar absorption tests (table 5) also showed that the O antigens of O group 127 strains and culture 2160-53 were closely related but not identical. The O antigens of these two sero-

types may be expressed by the use of arbitrary formulas, as follows:

4932-53 ----- O127a
2160-53 ----- O127a, 127b

It should be mentioned that all of the 121 cultures associated with sporadic cases and with epidemics of infantile diarrhea belonged to O group 127a, whereas the 9 cultures like 2160-53 were O group 127a, 127b. The former group of strains were nonmotile and somewhat less active as regards their biochemical reactions, and were further characterized by a distinct B antigen, as will be shown. The nine cultures of the latter group were motile (H antigen 4).

The relationships of the O antigens of *E. coli* O86a and O86a, 86b (5017-53) are given in table 6. The relationship of these two serotypes to each other was analogous to that noted between serotypes of O group 127, mentioned above. The H antigen of culture 5017-53 was not agglutinated by H antisera prepared with the 33 known *E. coli* H antigens. Thus, the H antigen of this serotype represented a new, unnumbered *E. coli* H antigen.

The results of reciprocal agglutinin absorption tests indicated that the O antigens of *E. coli* serotypes O86a, 86b, and O127a, 127b were related but not identical. A strong specific factor remained in each antiserum for the homologous serotype following reciprocal absorptions.

B Antigenic Relationships

When cultures of the *E. coli* serotype referred to as O127:B8 first were received in the laboratory for identification, they were tested on slides

Table 7. The relationship of the K antigens of certain *Escherichia coli* serotypes

¹ The K antigen of the *E. coli* O90 strain was undetermined.

with O and OB antiserum for the *E. coli* serotypes that have been associated with cases of epidemic infantile diarrhea. Living suspensions of these cultures were not agglutinated by any antiserum except that for O86, in which most of the living suspensions reacted to a greater or lesser extent. Living suspensions did not react in B7 (O86:B7) antiserum. The reason for this apparent discrepancy is believed to lie in the fact that the living O127:B8 strains were not entirely O inagglutinable and therefore reacted in the higher titered O86 antiserum and failed to react in the O86:B7 antiserum which had a relatively lower O titer. Heated broth antigens of several O127:B8 strains later were tested in O86:B7 antiserum and it was found that they reacted in dilutions of 1:160.

Living suspensions of the new *E. coli* serotype then were tested on slides in antisera prepared with all of the 61 known *E. coli* K antigens. Positive agglutination tests were obtained only in antiserum for B antigen 2 (O8:B2). In subsequent slide tests it was found that living suspensions of all 121 strains of serotype 127:B8 reacted in B2 antiserum. When K antigens prepared from representative strains of this serotype were titrated in serial dilutions of B2 antisera, all strains tested reacted in this antiserum at 1:40 but not in higher dilutions (table 7). A K antigen suspension made with a culture of *E. coli* O8:B2 did not react in OB antiserum prepared with serotype O127:B8.

The results of reciprocal agglutinin absorption tests (table 8), using living suspensions, confirmed the individuality and specificity of

thermolabile somatic antigens B2 and B8. That the thermolabile somatic antigen of *E. coli* O127:B8 was in fact a B antigen was shown by absorption tests in which all agglutinins were removed from OB antiserum for O127:B8 when the antiserum was treated with a heated (100° C., 1 hour) suspension of the homologous culture (table 8). The antibody binding power of the thermolabile somatic antigen was not destroyed by heat at 100° C. Since this B antigen was not identical with, or significantly related to, any described *E. coli* K antigen, it was designated "B5."

Two other undescribed B antigens were characterized during the examination of cultures related to *E. coli* O groups 86, 90, and 127. One of these was found in culture 5017-53 (O86a, 86b) and the other occurred in the nine cultures that belonged to O group 127a, 127b. The B antigens of these cultures were not related significantly to any known *E. coli* K antigen or to those described herein (table 7). The designation B9 was assigned to the thermolabile somatic antigen of culture 5017-53 and the comparable antigen of culture 2160-53 was designated B10. That these two thermolabile somatic antigens, B9 and B10, actually were B antigens was demonstrated by appropriate absorption tests.

It was possible to prepare pure B7 antiserum by absorption of O86a:B7 antiserum with unheated or with heated suspensions of culture 5017-53 (O86a, 86b:B9). Similarly, a pure B8 antiserum was prepared by absorption of O127a:B8 antiserum with either heated or unheated suspensions of serotype O127a, 127b:B10. These absorbed antisera agglutinated living cultures of the respective serotypes but did not react with heated suspension.

Summary

The biochemical and serologic reactions of 121 cultures of the new *Escherichia coli* serotype O127:B8 associated with infantile diarrhea are described. The cultures of the new serotype were isolated from cases of infantile diarrhea in three separate epidemics in Philadelphia, Pa., Cincinnati, Ohio, and Kamloops, B. C., and from sporadic cases of this disease in Mexico City.

Table 8. Comparison of the B antigens of *Escherichia coli* serotypes O127a:B8 and O8:B2

Antigen suspensions	B antisera				
	B2		B8		
	Unabsorbed	Absorbed by O127:B8 (unheated, forma- linized)	Unabsorbed	Absorbed by—	
				O8:B2 (unheated, forma- linized)	O127:B8 (100° C., 1 hour)
<i>E. coli</i> O8:B2, unheated.....	320	320	0	0	-----
100° C., 1 hour.....	2, 560	2, 560	0	0	-----
<i>E. coli</i> O127a:B8, unheated.....	40	0	160	160	0
100° C., 1 hour.....	0	0	2, 560	-----	0

The O antigens of the new serotype constitute a new *E. coli* O antigen group, 127, and the thermolabile somatic antigen of the cultures was found to be an undescribed B antigen which was designated B8. All of the 121 strains of serotype O127:B8 were nonmotile.

Two other *E. coli* serotypes, O86a, 86b:B9 and O127a, 127b:B10:H4, also are described. These two serotypes were isolated from normal individuals.

The O, B, and H antigens of the new *E. coli* serotypes are compared with those of previously described *E. coli* antigens and details of the relationships noted are presented.

• • •

Since this paper was written, and up to October 1, 1954, we have received 29 additional cultures of E. coli O127:B8, representing 43 additional cases of infantile diarrhea from outbreaks in Albany, N. Y., New Jersey, and sporadic cases in California and Chicago, Ill.

technical publications

Distribution of Health Services in the Structure of State Government, 1950

Public Health Service Publication No. 184, parts 1-4. 1954. By Joseph W. Mountin, Aaron W. Christensen, Evelyn Flook, Edward L. Mintz, Rubye F. Mullins, and Georgie B. Druzina. 360 pages; tables. \$1.90.

Distribution of Health Services in the Structure of State Government, a revision of Public Health Bulletin No. 184, third edition, 1940, is now available in a single volume. The four parts—Part 1. Administrative Provisions for State Health Services; Part 2. General Services and Construction of Facilities for State Health Programs; Part 3. Personal Health Services Provided by State Government; Part 4. Environmental Health and Safety Services Provided by State Government—each released under separate cover as the data were prepared, have been bound for the convenience of the reader in a

single publication, with a table of contents added. No revisions have been made in the material as previously presented in the separate parts.

State Tuberculosis Control Programs As Planned for Fiscal Years 1954 and 1955

Public Health Service Publication No. 396. 1954. 24 pages.

State program plans for tuberculosis control, fiscal years 1954 and 1955, are presented in abstract form in this booklet. Submission to the Public Health Service of a plan of operations for carrying out public health programs is required of all State agencies participating in Federal grants-in-aid for health work.

The abstracts reflect in concise form the proposed elements as described by the responsible State officials. No attempt was made to evaluate program content, and clarification of descriptions, interpreta-

tions, and editorial changes were kept to a minimum.

The booklet also presents a summary of the needs and problems significant to the tuberculosis control program as expressed by State program directors.

In addition, selected administrative information related to each State's tuberculosis control program is shown in tabular form. These data include placement of responsibility for tuberculosis control in the health department and staff assigned to the program.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

The Practice of Public Health, 1954

“**A**T THE BEGINNING of our school year at Harvard, I usually walk silently into the classroom and write on the blackboard the question, ‘What do the people want done about their health?’ The people must be part of our health team if our work is to be effective. . . .

“Learning people’s attitudes about health; having the value of their advice in planning; and giving them the opportunity to participate in working out their own health programs—this is helping people to help themselves, which has become such an important watchword in international health work. This is part of community organization and each of us in public health can understand its principles sufficiently well to make our work more productive.”

HUGH R. LEAVELL, M.D., DR.P.H.

Reader's guide on page 117

tion was the fact that the project was initiated by physicians—a group to which the community conceded a right to make decisions on health.

Before the action could be completed, he said, three stages in a pattern of social relationships had to be fulfilled—initiation, legitimization (the authority to justify action), and execution. There is sufficient regularity in human community behavior, he continued, to permit the trial in comparable community projects of the sociologic generalizations drawn from this situation.

Public Health Field Needs The Social Sciences

Can formal surveys provide a better understanding of community organization and function than daily experience has already given the regional health officer, the Community Chest executive, or the local politician?

Specifically, can the community self-survey technique, developed by social scientists, serve as an effective instrument for public health action?

These questions were posed by Odlin W. Anderson, Ph.D., research director of the Health Information Foundation, New York City, in the course of his remarks opening a symposium on community self-surveys in health. He gave no answers, but said that he trusted his listeners would have enough material to form their own opinions after all the talks were given.

During the sanitation and communicable disease stages, public health programs were rooted in the laboratory sciences, Anderson continued. But vital public health is now concerned with people and communities and is looking to the social sciences for assistance in the promotion, organization, and administration of its programs.

Public Opinion

It is in social and community organizations that health programs are

planned and promoted, he said, and it is there that they succeed or fail. Unless the programs are firmly supported by the general public, Anderson warned, they have little chance of success.

Physicians, nurses, sanitarians, health educators, and other specialists in the field know quite well the conditions which constitute health problems in a given area, he said, but they sometimes find that citizens of the community don't accept their conclusions.

There is always a lag between public health knowledge and its application, according to Anderson. He suggested that social science might shorten the present gap by providing techniques for the collection of data on social and community organizations.

Other Areas

Cost and utilization factors and legal problems associated with the planning and administrative phases of health programs are another area to which, Anderson believes, social science methods might be applied.

He also suggested that social science principles and techniques could be used in the study of the various conditions under which disease arises. In every time and place, he said, there is a disease pattern related in some way to such social conditions as the state of the arts and sciences, the level of living, composition of the population, and many other factors.

He concluded that, before the social scientist and the public health specialist can unite for effective work, each must learn more about the other's field.

Finds Experts Could Aid Community Self-Study

Communities cannot isolate themselves from resources and expert guidance available to them from beyond community borders and still do an effective job in study and action

problems in health practice, according to Floyd Hunter, Ph.D., associate professor at the School of Social Work, University of North Carolina.

Dr. Hunter was a member of the university's team which appraised the Salem, Mass., self-study. The 2-year appraisal, characterized by Hunter as a study of a self-study, was restricted to observing the social and power factors in the community organization and in the functioning of the self-survey.

The research team, Hunter said, found the community no exception to the general pattern of social stratification. Salem's study consisted of piecing together the opinions of a group of health agency executives related to their conceptions of health needs, he added.

Hunter also reported:

Salem did a complete study of health needs. It did not seek outside help in completing its study, nor did it call upon the observers for help.

If the community had had good outside help, it might have received more for its money.

Salem went about solving its health problems in a manner that conformed to its general pattern of problem-solving. Community functions in Salem are delegated to specific functioning groups, and, consequently, health organizations and their leaders had a greater interest in promoting and extending a health study than other community groups.

A small proportion of the total population was involved in the study, which was conducted by committee, behind closed doors, with public participation virtually limited to hearing the conclusions.

The formation of the self-study committee was subject to the general economic, political, and social processes that bear upon the local parent sponsoring body of the study, the community council.

Matters of communitywide policy in relation to health problems inevitably involved the community power structure. This was demonstrated in the relationship estab-

lished between the upper echelons of the power structure, mainly composed of industrial and commercial leaders, and the leadership of the committee, chiefly professional health workers and subleaders in the community. Committee members generally followed traditional role expectations.

A few leaders emerged in the survey process who were primarily instrumental in furthering the self-study. The health agencies and the members of the study committee were affected by the restrictions and limitations of the traditional social arrangements in the community. Salem's ethnic pattern showed a dominant minority, followed by five other minorities. The lack of social communicability between these conflicting groups has an important bearing on solving health problems.

There was no going into the details of agency operations, personnel practices, and the like, no depth in the examination of agency services or resources.

After all the pains and processes of study were finished, a health center was realized. Of several recommendations made by the self-study committee, the health center recommendation was the only one acted upon immediately. This immediacy of action reflected the interest of the health director and a few people close to him.

Alabama Study Action Came From One Group

Citizen participation in selecting health problems that need study is a device of crucial importance, said Solon Kimball, Ph.D., professor of education, Columbia University Teachers College.

This type of action, he explained, provides a mandate without which public health officers are less inclined to enter fields of possible controversy.

When people have an opportunity to examine conditions in their communities, proposals for improvement

carry widespread support, according to Kimball, who illustrated his discussion by showing application of the self-survey technique in a study of health conditions in Talladega, Ala. The study was made from 1951 to 1953 by residents of the city with the aid of a grant from the University of Alabama.

Citizen Participation

All decisions on scope, organization, and policy were placed in the hands of the community, Kimball reported. This arrangement, he said, pleased both the residents of the town, who were wary of probing outsiders, and the social scientists, who wanted to watch a community process unfold with minimum external disturbance.

Approval of the survey was readily secured from the county medical association and the board of public health, he continued. The chamber of commerce, which had initiated the study, then arranged for a series of public meetings and invited the principal institutions and industries and each civic, social, and religious group to send two delegates.

At these meetings, the citizens of Talladega elected a group to direct the survey and suggested health problems for this organization's study. Kimball said that some of the recommended items were garbage collection, city water fluoridation, school performance and health, Negro housing, stream pollution, and rural health. The newly elected officers based their program on these and other citizen recommendations.

University Observers

A team of social scientists from the university, Kimball continued, remained in the community as consultants and observers for the 2-year study period. Their major working responsibility, he reported, was to give technical assistance in constructing a communitywide questionnaire and in the use of sampling techniques.

The university team, he said,

avoided policymaking and leadership, but they sometimes raised questions or offered suggestions for smoother operation. Although community representatives were free to accept or reject their ideas, the social scientists, according to Kimball, took an active part in the project not only by providing technical skills but also by acting in the important role of catalysts.

Furthermore, he continued, they did so without impairing the basic responsibility of the community for its actions. When a community self-survey is well organized, he said, it can furnish enormously increased opportunities for the individual participation which is vital to the success of any group activity. The social scientist, Kimball remarked, may be able to further the process by stimulating isolated individuals and groups to work together on problems of mutual concern.

Pointing out that the town had 3 distinct social segments, he said that all of the planning and most of the activity were centered within the top third of the town's population although most of the problems considered were of equal or greater importance to the other two-thirds. The question of equalizing participation through all social classes remains unanswered.

Can Change Attitudes, End Misunderstanding

Self-surveys are designed to transform individual goals to community goals by stimulating personal and community participation in public health activities, stated Charles P. Murphy, research associate, Health Information Foundation, New York City. Such surveys also provide the health worker with a means of testing the degree to which health programs are understood, appreciated, and utilized, Murphy said.

Conflicting attitudes toward common problems change when persons from different parts of the community work together and learn to

understand each other and the causes of their misunderstandings, Murphy stated. Also, he said, persons who lack the initiative to work alone are usually able to take constructive action on community problems when they serve on committees and work with groups.

Health action programs are most successful when they are initiated through existing institutions and in accordance with usual community procedures, Murphy said. The self-survey technique encourages acceptance of programs which run counter to community traditions and uses the desire and ability of members of

a community to work together to solve their own problems. Timing of the program and selection of sponsors acceptable to the community are important, Murphy emphasized.

The probability of public support of a program is increased by self-surveys, Murphy concluded. Large segments of the community become personally involved and personally interested during the initiation, fact-finding, and planning stages of a public health program and develop a sense of personal responsibility toward the situation being studied, he said.

Suburbia and Public Health

"Horse and buggy public health is not good enough to deal with the problems of suburbia," APHA President Hugh Leavell, M.D., Dr.P.H., said in concluding two half-day sessions participated in by public administrators, political scientists, historians, and business representatives, as well as public health leaders, on the topic, "The Impact of Suburbanization on Public Health."

"There must be understanding of the 'frontier fantasy' and of the objectives people have in going to live in suburban areas," Leavell said. "As they become migratory workers going into Central City in the morning and returning to their bedroom communities in the evening, we must understand the resulting changes in family structure and function and consider how our health advisory functions need to be adapted to the problem," he said.

"We need a child's 'bill of rights' as well as a GI bill of rights, since it seems likely that the child suffers more from being in suburbia than does his mother or father who usually have had the advantage of being brought up in areas where there were suitable cross-cultural influences and

where they experienced the interdependency and neighborliness of a balanced community," Leavell concluded.

At the opening session, members of the APHA General Program Committee reported from a specially prepared analysis of the problem. Key facts given were:

The greater part of the population in this country is established in 168 "urban sprawl" areas. These areas occupy 7 percent of the land in the Nation. Suburban areas are growing in population at a rate greater than the central cities. But the central cities are still growing.

The "spill" of urban population has produced a complex web of interrelated issues affecting schools, mental health, drainage, water supply, transportation, hospital facilities, and sewage and garbage disposal.

The 77 standard metropolitan areas which have cities of 50,000 to 100,000 include almost 5,000 independent governmental jurisdictions. There are 16,210 units of local government in the 168 areas. Eleven have more than 250 units each.

Summing up the opening discussion, Abel Wolman, Dr.Eng., professor of sanitary engineering at Johns Hopkins University, attributed the process of suburbanization to uncritical developments of transit facilities, easy credit terms for automobile purchases, and the rise in population. At the root of the urban difficulty, he said, was the fact that private individual decisions conflict with the best of community plans.

The consequence of the failure of urban communities to plan for growth, Wolman stated, is the cultural and physical deterioration of the countryside.

Meanwhile, he said, the central core of the city, still holding the major share of the population, has its own drastic needs of housing, schooling, medical care, traffic facilities, accident prevention, and sanitation. These needs it must attempt to satisfy while its wealthiest and most influential community leaders desert the towns for rural retreats.

The second session of the symposium discussed remedial action for the cities which, said Victor Jones, Ph.D., professor of government at Wesleyan University, pursue three general policies:

1. Do nothing.
2. Organize each interest in a separate unit: water, school, sewerage, housing, traffic, and so on—a policy having the advantage of being an easy course but replacing territorial disintegration with functional disintegration.
3. Organize a regional government to weigh needs and resources and to share responsibilities with local units of government.

Jones warned that a regional authority, if it is not subject to popular control, may be unresponsive to popular needs and desires, and he suggested that a county government, properly organized, can do anything a regional authority can do. He also supported the proposition that services necessary for the well-being of the whole community need not be self-supporting on a fee, license, or special tax basis, but would warrant

financial support out of general tax revenues.

In suggesting guidelines for urban management, Leona Baumgartner, M.D., Ph.D., commissioner of health, New York City, observed that economies may be realized by rehabilitating the neighborhoods and lives of that 6 percent of the so-called problem families which consume more than half of public welfare services.

Dwight Metzler, chief engineer, Kansas State Board of Health, recommended economies by organizing sanitary districts for management of water and sewer facilities.

Leroy Elwell of the Pennsylvania Economy League described the operation of the Pittsburgh-Allegheny County plan.

Paul Lemkau, M.D., and Ruth Freeman, Ed.D., of the Johns Hopkins School of Hygiene and Public Health, discussed the sociological and psychological implications of

stratifying American neighborhoods according to income level, occupation, or ancestry.

Howard Ennes, M.P.H., director, bureau of public health, Equitable Life Assurance Society, chaired the panel.

Participants included, in addition to those named above:

Marvin Rapp, New York State College for Teachers, Buffalo; A. Holly Patterson, LL.B., County Executive, Nassau County, Mineola, N. Y.; Dorothy Nyswander, Ph.D., University of California School of Public Health; Granville W. Larimore, M.D., M.P.H., New York State Department of Health; Berwyn F. Mattison, M.D., commissioner of health, Erie County Health Department, Buffalo; William C. Spring, Columbia University School of Public Health; and Roscoe P. Kandle, M.D., deputy commissioner of health, New York City.

tween State and local public health laboratories was limited to the situation in California.

Direct Services

Tests performed by that State laboratory in one area of public health activity—direct services to physicians and health departments—vary with the size and facilities of local organizations. But in general, Bodily reported, they include virology, mycology, and parasitology examinations. The State also provides the tests most logically centralized in one laboratory, such as enteric phage and sero typing, food and drug examinations, and specific identification of problem cultures.

The local California laboratories, said Bodily, perform general serologic and bacteriological tests and give examinations the State cannot conveniently provide because of transportation and related problems.

Other Services

Only a few State laboratories, according to Bodily, engage in biological production. Their standardization of biologicals is more important and often consists in evaluating various products and sending test results to local laboratories and manufacturers.

The extent of research programs varies widely among State laboratories, he continued, but most of them are in a position to search for new techniques and evaluate those which are proposed. He said research was well suited to the general consultative character of most State organizations and recommended the aid and encouragement of increased research activity at the local level.

Many States have an evaluation and approval program for their local organizations, Bodily reported. In some cases, it is only for 1 or 2 procedures. In others, it covers every phase of laboratory work and includes certification of personnel. These procedures benefit the State laboratories, he continued, by showing them how much confidence to place in work done at the local level, while public health personnel scat-

Laboratory Grants and Research...

The State and local laboratory areas of performance, their relationships, and their eligibility for PHS research grants are the subjects of three of the papers in this section. Research offerings include a test for identifying pathogenic fungi in sputum, a refined trichinosis test, improved microscopes, and the findings that streptococcal infection is spread mainly by direct contact, and that persons infected with Mycobacterium leprae react specifically to the standard tests for syphilis. Lowered skin resistance is suggested as an etiological factor in fungus infection of the feet.

Laboratory Can Do Much To Assist Others

Some public health services from State laboratories reach residents of all areas, and people in isolated localities depend on them almost completely, according to Howard L. Bodily, Ph.D., chief, division of laboratories, California State Depart-

ment of Health. This, he said, is a natural result of a division of activities by type of service and geographic boundary between State and local public health organizations.

Specific activities have been assigned to State and local organizations according to a variety of systems, he said, but the first part of his discussion on the relationships be-

Discussing isolation and identification of pathogenic fungi from sputum, Kurung outlined details for collection of the material.

Preliminary Steps

Sputum should be obtained early in the morning and should come directly from the lungs. Saliva and nasopharyngeal secretions should be avoided.

The sputum should be carefully examined with a hand lens for the presence of the yellow or gray *Actinomyces* granules. Stained and unstained preparations of the tiny particles should then be examined microscopically.

The particles or other specimens of sputum for this examination should be placed on a glass slide and mixed thoroughly with one or two drops of 10 percent sodium hydroxide. A glass cover is then placed over the preparation and, after 3 to 5 minutes, it can be examined under subdued light for fungi.

Sputum Cultures

The identification of fungi, except for *Actinomyces bovis*, *Blastomyces*, and *Coccidioides*, is difficult by direct examination of sputum, Kurung said. In all cases, diagnosis should be confirmed by cultural methods. Typical cultural and morphological fungus characteristics, he stated, are best demonstrated by the simultaneous use of brain-heart infusion blood agar and Sabouraud's glucose agar media.

The first culture medium is prepared by adding 10 ml. of blood, 2,000 units of penicillin, and 4,000 mcg. of streptomycin to each 100 ml. of Bacto brain-heart infusion containing 2 percent agar. Streak a generous loopful of purulent sputum over the plates' surface, seal the plates with wide rubber bands to prevent drying of the medium. Two blood agar plates are incubated at 37° C., and two blood agar plates and the two Sabouraud's plates at room temperature. If actinomycosis is suspected, anaerobic cultures on

brain-heart blood agar without the addition of the antibiotics should also be made.

If periodic examination shows that the plates are negative, they can be discarded after 4 weeks of incubation.

Identification

The pathogenic fungi, Kurung continued, are markedly different in appearance, both culturally and microscopically. Recovered colonies may be smooth or rough or cottony and filamentous with abundant aerial hyphae. Microscopic examination, he said, should be made of an unstained slide preparation from the colony.

Fungus identification, said Kurung, is based on the type of colony recovered, the appearance and location of spores, the presence, size, and shape of yeastlike budding cells, and the presence of arthrospores and chlamydospores.

Hansen's Disease Patients React to STS Antigens

Serologic tests of persons infected with *Mycobacterium leprae* may provide a valuable indication of the specificity of the lipid antigens used in standard tests for syphilis, according to John F. Kent, Ph.D., chief, and Robert E. Harrigan, department of serology, Army Medical Service Graduate School, Washington, D. C., and A. Garcia Otero, M.D., Havana, Cuba.

Kent and his associates reported results of a study of 34 native Cubans infected with *M. leprae*. None of these patients showed either clinical or anamnestic signs of treponematoses, and all of them were negative for treponemal immobilizing antibodies.

The eight serologic tests for syphilis used in the study included flocculation and complement fixation tests, and if a serum reacted to one or more of the tests, the degree of reaction was determined quantitatively, Kent and his co-workers said. They stated

that ordinary extracts of beef heart used as antigen produced the greatest number and the strongest reactions, whereas cardiolipin antigens produced a relatively low but variable frequency of "false" reactions. Fifty percent of the persons examined reacted to the Kahn standard test; only 12 percent reacted to the Army Medical Department's cardiolipin complement fixation test.

Report the Refinement Of Trichinosis Test

Refinements of a complement fixation test for trichinosis, reported by Victor N. Tompkins, M.D., and Thelma Murasch, B.S., of the division of laboratories and research, New York State Department of Health, produce highly specific reactions and permit early detection of infection. Reaction persists only 6 to 18 months following infection.

Three types of tests for trichinosis depend upon reactions with humoral antibodies which develop during the course of *Trichinella spiralis* infection in man. Known as skin, precipitin, and complement fixation tests, their relative merit has been moot. With all of these tests, laboratory workers have encountered nonspecific results from cases known to be infected.

Using an antigen improved by Witebsky, Wels, and Heide, several investigators had found that the complement fixation test of human serums had excellent specificity and greater sensitivity than skin or precipitin tests. Nevertheless, the test continued to fail to induce a reaction from serums of certain patients known to be infected. Tompkins and Murasch sought to reduce such failures by improvements in the technique of testing.

Three technical factors were found to influence the sensitivity of the test after many failures resulted from the use of an antigen level which had produced a maximum reaction from a single patient. One factor was that

undiluted serum often inhibits a reaction. It was recommended that serum should be tested not only undiluted but also in saline dilution 1:5 for this test.

The amount of antigen was the second factor. It was recommended that a wide range of antigen dosage be applied not only to establish maximum reaction but to detect reaction at all. Examinations of serums from more than 30 patients indicated that no single amount of antigen will detect reaction, whatever the concentration of the complement, but that three amounts can be expected to detect all reactions. The experience indicated the use of dilutions of 1:8, 1:64, and 1:128 in the presence of three units of complement.

The third factor was the amount of complement. Three instead of six units of complement increased sensitivity and in some instances allowed earlier diagnosis.

Reactions have been observed as soon as the first week of symptoms. In most instances, specimens collected between the 16th and 21st days of illness are the first to react. Reaction from one asymptomatic patient, however, was not obtained until 8 weeks had passed. Titer rises rapidly at first, reaches its maximum in the second or third month, then slowly declines.

Discusses Improvements In Microscope Design

Although microscope design has been considered comparatively stable, significant improvements in mechanical and optical design have been made in recent years, according to James R. Benford, head, visual instruments department, Bausch and Lomb Optical Company. More improvements are indicated in the near future, he added.

The mechanical design is often the deciding factor in the performance of a microscope in doing a given job, he said. Within the last few years

the standard microscope has been improved in stability, in durability, in manufacturability, and in convenience of operation, he reported.

The use of ball bearings in the adjustment mechanism of microscopes provides frictionless fine adjustment accurate to within a small fraction of a thousandth of an inch,

he claimed, and greatly prolongs trouble-free durability of the mechanisms.

The introduction of phase microscopy, improved design of microscope eyepieces, and new instrumentation for ultraviolet microscopy are examples of improvement in optical design, Benford said.

Improvement in field coverage made possible by newly designed eyepiece using high index glass.

Comparison between a bright field image (left) and a phase contrast image of mineral dust particles.

"Mr. Who" Comes to Thailand

"I cannot resist telling an amusing but pertinent story about the World Health Organization, which is known in many parts of the world as WHO. An Indian doctor working on malaria control in a remote village in northern Thailand asked the local headman a few questions: Had he heard of Mr. Nehru? 'No' was the answer. Had he heard of President Eisenhower? 'No.' Had he heard of the UN? Again, 'no.' Had he heard of WHO? 'Oh, yes,' the man replied, 'Mr. Who is the man who sprayed my house, and we have had no more sick babies—a very good man.'"

—DAVID MCKENMEE KEY

selves with the needs of these people, he added.

As for the people receiving WHO assistance, they are discovering that cooperative international action can achieve tangible benefits for them in their own lives, Key explained. They are discovering also, sometimes for the first time, that they themselves can actively participate in measures to improve their conditions. Apparently insignificant events, such as a mother taking her child to a rural health center or a village population working together to construct a sanitary well, often represent a new awakening of individual and community initiative, he said.

Democratic Principles

Not only in its activities is the WHO helping to promote democratic ways of life but also in its organizational structure, the Assistant Secretary noted. In this respect, he stressed WHO's use of regional offices and regional committees, which, he said, enable it to be particularly responsive to the wishes and needs of member states.

Key outlined the procedure as follows: First, nations discuss with the regional office staffs their needs for various types of WHO assistance. Then, regional committees meet to discuss health needs and to review a health program for their areas. Only after this regional review are the programs submitted

to WHO headquarters for integration into an overall annual program and for final approval or modification by the annual world health assembly.

WHO Consultant Recounts Experience Overseas

"The most impressive person I met in Yugoslavia was . . . a health officer whose area was in a difficult terrain and whose people suffered because their diet was deficient in protein. With a reformer's zeal and a diplomat's finesse, he had persuaded his people to dam up a stream to build a small lake, not for hydroelectric power, but to grow fish."

This was one of the incidents related by Paul V. Lemkau, M.D., associate professor of public health administration, Johns Hopkins University School of Hygiene and Public Health, in an informal report on his 6-week tour of Yugoslavia in 1951 as consultant for the World Health Organization.

The prevailing topic of discussion as the consultants and their Yugoslavian hosts traveled over the rough and winding roads of the country, particularly in Serbia, Bosnia, and Macedonia, Lemkau recalled, was the condition of the toilets. They usually wouldn't work at all and were far more unsanitary than pit

privies, he said. One of the Yugoslavians advocated an educational program to get the situation improved, while another contended that a law should be passed, thus provoking the basic philosophic argument of force versus education, the WHO consultant noted.

At the end of World War II, Yugoslavia directed its attention to social reform, particularly toward improving the care of children, Lemkau said, noting the prevalence of institutions for children, from nursery schools for children of working mothers to institutions for adolescents. The specialized but briefly trained teachers called defectologists seemed, for the most part, to be doing good work, he said. Foster care was just beginning to be tried out, and the workers using it were enthusiastic about the early results.

Observations in Japan

From a similar tour in Japan in 1953, Lemkau reported that in general the Japanese had much knowledge but that they tended not to use it because of lack of funds or, sometimes, because the knowledge was not associated with a real drive to change things. For example, he said, everyone seemed to know that fever was no longer really needed for the treatment of paresis; yet it was almost universally used. Perhaps the fever boxes were so hard to get, Lemkau suggested, and so costly that the Japanese did not want to give them up.

Disease Control Efforts Prove Effective

The work the World Health Organization has done in bringing order out of the chaos of international quarantine was cited as one of its noteworthy achievements by Arthur S. Osborne, M.D., international health representative of the Public Health Service.

Together with its system for disseminating epidemiological information, the International Sanitary

Regulations of the WIHO have set up an almost impervious barrier against the importation into this country of the so-called convention diseases, Osborne specified.

As an example of the value to the United States of WIHO's reporting system, he mentioned its effectiveness in connection with the recent occurrence in Trinidad of the first cases of urban yellow fever in 20 years. Pointing out that one-third of the United States is a yellow fever receptive area, he said that the reporting system has given us time to set in motion the machinery necessary to exclude the disease.

Rabies Control Efforts

Osborne cited rabies as one of the diseases which shows the effect of action among the community of nations making up WHO. More dramatic even than the mass vaccination campaigns, he said, is the announcement of the result of the study sponsored by the WHO on the use of hyperimmune serum. There is now evidence that this material, which is used in conjunction with vaccine, will confer immediate passive immunity that will protect a person exposed to rabies until an active immunity is built up by the vaccine.

Rabies, endemic throughout the world except in certain limited areas, has been no small problem to the United States, particularly in the southwestern States since the disease is hyperendemic in Mexico, Osborne noted.

Concerning mass vaccination campaigns, he mentioned the field tests of avianized rabies vaccine in Israel and Malaya, where the disease in its enzootic form has been a serious problem. In Israel, after 3 years of mass vaccination of dogs, only five cases of rabies in animals were reported in 1953. In Malaya in August 1952, just before the start of the mass immunization program, there were 41 cases of laboratory confirmed rabies; by June 1953, the disease had disappeared from the country.

In Mexico, an intensive antirabies program has resulted in a drop from 37 human cases in 1952 to 4 in the first 7 months of 1954, he said. A similar reduction is apparent in the United States, the number of cases dropping from 21 in 1952 to 5 in the first 9 months of this year.

Osborne also mentioned the WIHO work on controlling traffic of addiction-producing drugs, the standardization of biologicals, and the International Pharmacopoeia as part of the measurable benefits the United States has received from its participation in WHO.

Indonesians Receptive To Health Program

Widespread information about health problems and a universal desire for better health services were found by John C. Hume, M.D., Dr.P.H., in Indonesia when he visited the country early in 1954. He believes it inevitable that the country will attain a high level of health services, given only time, moderate assistance, and freedom from war.

Dr. Hume, associate professor of public health administration and assistant director, Johns Hopkins University School of Hygiene and Public Health, was in Indonesia as a World Health Organization consultant. His major assignment was to review the yaws eradication project. This project, he said, is only one of many health programs in the country and one of several joint ventures of the national government and the World Health Organization.

A tour of the island of Madura in the company of its regent and vice regent enabled Hume to observe how deeply interested Indonesia's civil leaders are in health problems and programs. Not only did they have a detailed knowledge of the yaws eradication program—of how much work had been done and of how much remained to be done in their regency—but they had good general

information about the disease itself. Moreover, they had an intelligent grasp of the health problems facing Madura, in terms of both specific diseases and the difficulties posed by shortages of trained personnel. The leaders expressed to Hume their interest in broadening the health programs and in raising the level of general medical and public health practice.

A major problem in Indonesia, with its 80 million people scattered over some 2,000 islands, is that of transporting men, equipment, and supplies from one island to another, Hume pointed out. That the task of providing health services in this country is an enormous one is demonstrated, he said, by the fact that in 4 years, the yaws eradication program has been able to reach only about 15 percent of the people.

Combating Yaws in Haiti

Although Haiti has social, economic, and health problems comparable to those of Indonesia, it has made considerably greater progress in combating the problem of yaws, according to Hume's report. Since the yaws eradication project began in February 1951, almost all the country's 3½ million people have received treatment, and, according to the latest estimates, the percentage of the population demonstrating lesions of yaws has dropped from about 15 to less than 0.03, he announced. He served as a WHO consultant in Haiti for 2- to 6-week periods during each of the past four summers.

The dramatic results of the program are apparent to all the population. "The news travels far and wide by word of mouth and probably by drums as well. In the early days of the campaign, it was not unusual to see persons crippled with crab yaws who had hobbled 30 to 40 miles to receive a penicillin injection. More difficulty was encountered in preventing persons from moving along with the treatment teams and receiving therapy in successive villages than in persuading reluctant

individuals to receive treatment," Hume said.

Commenting on the future of public health work in Haiti, Hume reported that the health authorities are planning a broadened program and that the citizens are eagerly awaiting the new services. New programs must, of course, come gradually, as financial limitations and shortages of public health personnel permit, he noted.

Overseas Health Programs Sow Seeds of Democracy

In helping to raise social and economic standards in the underdeveloped areas of the world, public health can be used to prevent communism from taking root and can strike at its most vulnerable point, according to John A. Logan, Sc.D., chairman, department of civil engineering, Northwestern University Technological Institute.

Logan warned that the United States could lose leadership in the practical application of technology in the undeveloped areas, unless planning is unified and the need for cooperation with local communities is more appreciated.

Public health workers have served for more than a century as a "social conscience" with regard to the improvement of health and sanitation in the United States. They must now apply the same approach to the world, he said.

Logan suggested that a key to the future success of our overseas development program lies in the willingness of health officials to work with nonprofessional groups and to accept leadership in the broad field of development. He pointed out that this is of particular importance to the health engineer because of the contribution that the engineer can make overseas to environmental sanitation. Likewise, engineering training gives the engineer special competence in the collection and im-

partial evaluation of data and opens opportunities for leadership.

Community Development

Logan pointed out that this country has developed technical competence in the field of regional planning. He cited the Tennessee Valley Authority as an example. He urged greater knowledge of multipurpose community improvement, which he termed "the keystone to successful large-scale foreign operations."

As known today, the community development concept evolved in China from the mass education movement of the 1930's from which came sufficient experience to establish the following basic needs, which Logan expressed as the principles of self-help:

The need for regionalization—the incorporation of groups of communities within a rational administrative unit.

The necessity for community or village committees and voluntary workers as the basis of the self-help movement.

The need for a multipurpose approach—although an important objective of development is self-sufficiency in food production, it is now recognized that increased agricultural production cannot be brought about on any important scale unless the twin obstacles of disease and ignorance are simultaneously attacked.

The necessity of providing priorities with regard to the objectives of development, usually beginning with the satisfaction of "felt" needs.

The necessity for the removal of the economic and social obstacles to the dignity and development of the individual, including such factors as cultural prejudice and the feudal barriers to the ownership of land.

"Community development should not be looked upon as a specialized branch of any particular government department," Logan added, emphasizing that regardless of how this

fundamental technique of development is administered it should provide an integration of all departmental interests at the village level.

"The active participation of local people in their own betterment not only alters the attitude toward development from that of an imported foreign procedure to something understood and appreciated, but it directly utilizes one of the most important capital resources of the underdeveloped areas, the productive capacity of the population," he noted.

WHO and United States Cooperate in Iran

The bilateral programs of the United States can create a greater impact with their greater financial resources and through their more direct relationship with host governments, but the multilateral approach of the World Health Organization is really the long-range approach to technical assistance, declared Emil E. Palmquist, M.D., M.P.H., who served as chief of the public health division of the United States Operations Mission to Iran from 1951 to 1953. He is now assistant chief, Division of International Health, Public Health Service.

Palmquist gave several examples of the close working relationship established in Iran between the United States mission and WHO personnel. One was the malaria control program, which was guided by a malaria control commission made up of representatives from the Iranian Ministry of Health, the School of Medical Sciences of the University of Teheran, a WHO advisory unit, and the United States mission. Another was a tuberculosis control demonstration center, for which WHO provided seven technicians and the United States mission supplied administrative services and some of the equipment.

Describing briefly some of the public health activities under way in this

country, Palmquist emphasized the malaria control program, which he said has produced spectacular results. In the Caspian Sea area, for example, the incidence of malaria dropped from 90 percent in 1949 to 9 percent by the end of 1953, he reported.

Other programs mentioned included an extensive environmental sanitation program; demonstration health centers, which emphasize the training of sanitarians and women health visitor-midwives; programs involving acute communicable disease, trachoma, tuberculosis, and venereal disease; and an extensive health education program.

Technical Aid to Vietnam Stimulated Local Action

Speaking from his 2 years' experience with the United States technical assistance program in North Vietnam, Warren Winkelstein, Jr., M.D., M.P.H., declared that the program has led to improved public health operations in that country not so much through the provision of any specific technique as through the stimulation of action and the exchange of ideas. He considered particularly important the help given local personnel in developing confidence in their own capacities.

Dr. Winkelstein, now director of the division of communicable disease control, Erie County (N. Y.) Health Department, was regional representative for North Vietnam of the public health division, United States Special Technical and Economic Mission to Indochina, from 1951 to 1953.

The relationship of the foreign technician to the local health worker was early recognized as one of the problems to be met in this country, Winkelstein reported. It was necessary to establish confidence on the part of the local officials in the fact that there were no strings attached to the technical aid, he said. It was necessary further, he specified, to

help the health department leaders develop enough confidence so that they could undertake activities of a scope not previously envisioned and so that they could sustain ordinary failures without losing perspective.

Winkelstein attributed the local health personnel's reluctance to proceed with programs and their emphasis on the need for material aid to the fact that responsibility for activities was comparatively new to them. They therefore clung tenaciously to tangible objects and were afraid to venture into actions results of which were not entirely predictable, he contended.

Health Problems and Programs

Discussing the conditions in North Vietnam at the beginning of the technical assistance program, Winkelstein noted that outside the cities of Hanoi and Haiphong there were

only 3 or 4 physicians and that there was an almost complete lack of medical facilities in the rural areas where most of the people lived. He listed as the major health problems trachoma, smallpox, infant mortality, gastrointestinal diseases, malaria, and tuberculosis.

A field program for the treatment of trachoma and a village dispensary program were two of the United States assisted projects that Winkelstein described. The latter program, which he thought was perhaps unique, involved the provision of a kit of drugs and medical supplies to any village that would send a local person to a training institute for 2 weeks, would furnish a suitable location for the dispensary, and would make the treatment available to the people without charge. More than 1,000 villages established these dispensaries, he reported.

Programs in Dental Health . . .

Emphasis on dental care for children; the use of educational techniques; and clinical research in such fields as oral pathology, periodontal disease, and the growth and development of dental structure in children are features of five programs designed to promote dental health.

Michigan Gathers Data On Child Dental Care

The most effective approach in a dental corrective program is to begin with the younger children, correct all existing dental defects, and then recall the patient periodically for maintenance work. With this working hypothesis and with a statewide program as an objective, the Michigan State Health Department established a dental clinic in Sturgis in 1945. Data on the time required to care for dental needs of Michigan children as well as infor-

mation on the annual increment of caries were collected by the clinic.

Charles J. Donnelly, D.D.S., M.P.H., dental officer in the public dentistry section of the Michigan State Health Department, presented the findings of the pilot study. The data, he said, substantiate the conviction that the benefits are not limited to the group under treatment but extend to other children and even to adults in the community.

The Plan

With the cooperation of local dentists and school authorities and

with the approval of the Michigan State Dental Association's Board of Trustees, the plan was carried out in Sturgis (7,000 population) because it had never had any kind of dental health program.

Donnelly reported that the initial care program was limited to pre-school, kindergarten, and first and second grade children; that once the child's accumulated dental needs were cared for, complete maintenance care was given periodically; that the plan provided for the addition of a new group of children every year; and that maintenance care for a 12-month period required between one-third and one-half the time needed for the initial correction of accumulated defects.

To determine how many parents would accept dental care for their children, no concentrated educational program was undertaken at first to enlist them, Donnelly said. In the beginning, 73 percent of those eligible took advantage of the clinic facilities. Acceptance, he said, varied from year to year with the effort expended to explain the objectives and value of the program, and—as the reputation of the clinic gained—finally approached 100 percent.

High standards were set and a high quality of service was maintained, Donnelly said. For instance, bitewing radiographs were taken annually and other radiographs when necessary, in addition to treating carious teeth, removing infected teeth, pulp-capping, pulpotomy, castings, and analysis of saliva samples. Lactobacillus counts and caries history determined the number of recalls, which averaged two per year.

The individual services given by the dentist were timed by the assistant. It was found that a full year of maintenance care requires only about 1 hour of dentist chair time (up to the age of 12 years), he said.

Donnelly cited statistical results which, among others, showed: that the time required for initial care of accumulated defects ascended from 83 minutes for the average 5-year-old to 173 minutes for the average 9-

year-old; that maintenance care varied from 56 minutes for the 7-year-old to 128 minutes for the 14-year-old.

A 5-year evaluation of the plan was made in 1951. Much of the data is yet to be analyzed, Donnelly reported. The Sturgis program employed one dentist and at the close had nearly 800 active cases under treatment.

Clinical Dental Research Probes Into Many Areas

Patients are being studied at the National Institute of Dental Research to obtain more information on problems in such fields as oral pathology, periodontal disease, and the growth and development of dental structure in children, said Ralph S. Lloyd, D.D.S., chief of the Dental Department at the National Institutes of Health Clinical Center, and acting chief of the NIDR Clinical Investigations Branch.

In the first year of the Clinical Center's operation, Lloyd said, National Institute of Dental Research investigators began several laboratory, field, and clinical research studies of dental problems. Among the particular interests of NIDR research workers are those problems—such as chronic stomatitis, gingivitis, and leukoplakia—demanding combined medical and dental attention. The complete and detailed series of diagnostic and other tests carried out for each patient at the Clinical Center offer valuable material for such investigations, he continued.

For instance, a study of the systemic condition of persons with periodontal disease was recently undertaken. A method of gauging the severity of this disease, which involves tissues surrounding the tooth, proved valuable in field studies and was given a successful clinical trial. It was found, according to Lloyd, "that an accurate periodontal score could be assigned by a cursory glance." The patient's clinical rec-

ord is then examined for conditions which may be correlated with the periodontal finding.

Fluoride Studies

Three of the research studies which Lloyd reported deal with fluorides. An epidemiological survey of the physiological effects of fluorides in the drinking water of two population groups is being conducted. A related investigation is concerned with the possible histological or chemical changes in individuals who live in high-fluoride areas. Lloyd described the third investigation as a "carefully conducted balance study" in the measurement of fluoride turnover for patients with cardiovascular or renal diseases as compared to the turnover for normal persons in control units.

Other Fields

In the field of growth and development, more simplified ways of treating specific types of malocclusion are being sought. Lloyd said that other projects in this field include continuation of research begun elsewhere, such as the study of the growth and development of the heads of young children who have cleft lips and cleft palates, and of children with other congenital and acquired anomalies.

Data are to be accumulated on general anesthesia used in oral surgery to aid in the evaluation of the new, intravenously administered drugs. Also, investigators plan to begin a study of cysts of the mandible and maxilla.

A comparison of conservative and radical surgical techniques in the treatment of periodontal disease has been started, so that, with other clinical investigations, NIDR research workers may develop diagnostic criteria which will help to forecast the result of treatment.

Future Plans

Other studies suggested include studies of the effects of radiation on oral health and oral infection, of the effects of steroids, hormones and re-

lated substances on oral lesions, and of dental prosthetics. An investigation in the last named group would deal with tissue tolerance to the prosthetic appliances. A study intended to discover ways of determining a definite working and rest bite in prosthetics has also been suggested, according to Lloyd.

Assign Learning Programs To Education Specialists

In conducting educational programs in dental health, the health department should seek assistance from specialists in educational methodology, suggested H. Shirley Dwyer, D.D.S., director, division of dental hygiene, Arkansas State Board of Health.

He described an experimental dental health teaching project which demonstrated that by stimulating the school teacher's interest and by providing the facts the teacher was able to transmit the health lessons to the school children in an understandable form and integrated with the regular school subjects.

The use of a health coordinator in each of Arkansas' schools resulted subsequently in the appointment by the State Dental Society of Arkansas of a dental coordinator for each school, he said. The coordinator supplies the teachers with dental information, checks expenditures for educational materials, and helps stimulate greater efforts in promoting dental health. He is the dental society's representative to the conferences called by the State departments of health and education. His position offers a practical means of promoting dental health education at the local level.

The Dental Columnist

Dwyer said the press could be invaluable in promoting a dental health program. He pointed out that in preparing a daily column a person with newspaper training could translate the technical terminology of a

profession into the "earthy" language of the people, and also could take a local slant on items. A chatty style, colorful use of familiar words, and short sentences are necessary, he said, in warning that much material intended to be educational results in being only promotional.

In discussing use of radio and television for dramatizing public health programs, Dwyer cautioned that care be taken to make one point of emphasis only per broadcast. "Do not throw the entire dental textbook at them in 15 minutes," he said.

"Get the community interested in doing," Dwyer advised. Organize a community health council and point the way so that it can discover its own community needs, and, he added, the desire to meet these needs is almost sure to follow.

Maryland Dental Service Stresses Child Care

An evaluation of the Maryland dental service program after several years of operation showed that a too high proportion of expenditures was going for prosthesis and too little for children's dentistry, according to Richard C. Leonard, D.D.S., M.S. P.H., chief of the division of dental health, Maryland State Department of Health.

To reverse these proportions, he said, children's services were expanded to include school dental clinics for all children.

The revised prosthesis service policy authorizes dentures for eligible persons 45 years of age and younger. Persons over 45 years of age must obtain approval of need for the denture from the County Advisory Committee on Medical Care. A decision based upon the financial status of the program in relation to the patient's financial and medical status is made.

Leonard reviewed the State's medical care program beginning with its reactivation period in 1939. Legislation, effective June 1, 1945, placed

the program under the guidance of the new State Council of Medical Care. All services at that time were limited to the indigent, said Leonard. The dental service program was an integral part of the medical care plan.

Control and administration, so far as possible, were initially handled by county authorities and county professional groups. This made the extent of services vary from county to county, Leonard pointed out. Uniformity of program has now been achieved, he explained, and both the amount of service and the character of service have changed during the years. For example, fluoride therapy and prosthetic service are now offered, more emphasis is now placed on preventive dentistry, and the school dental clinic work has greatly expanded and now requires no economic limitation for children.

Dentists Cooperate

In 1952, approximately 50 percent of the Maryland dentists practicing in county areas participated in the dental care program, Leonard said. On each county advisory committee a practicing dentist represents the profession, another of many evidences of the cooperation of the dental profession in helping to develop the program, he noted.

Leonard recognized as justifiable the criticism of the low fees paid to participating dentists. This shortcoming, however, is governed by a legislatively determined budget which limits ability to raise fees.

In behalf of the dental fee schedule, Leonard said the fees are the high average of those suggested by county dentists and that too high fees would have threatened to defeat the entire program. Prior to the inauguration of the program, he pointed out, dentists gave a great deal of free service to the indigent and the medically indigent. The present fee schedule is at least some reward, he felt.

The indigent population of Maryland has varied between 13,000 and

17,500 persons, better than 50 percent of whom may be classified as aged persons (over 6,000 are over 65 years of age). About 31 percent of Mary-

land's indigents are under 20 years old and only approximately 12 percent are between 20 and 46 years old, said Leonard.

cumulative effects of exposure to small quantities of chemical and physical contaminants of air and water, Andrews concluded.

To obtain etiological and epidemiological information about the consequences to human health and effectiveness of exposure to these substances, the sanitary engineer, he believes, will need to work closely with the toxicologist, the pulmonary physiologist, the pathologist, the roentgenologist, the radiologists, occupational health specialists, and with other sanitary engineers.

The Sanitary Engineer . . .

The many and complex problems of environmental sanitation and the challenges they present to engineering research are discussed. The new research program being developed by the Lawrence Experiment Station of the Massachusetts State Department of Public Health is described.

Epidemiologist-Sanitarian Collaboration Urged

New environmental controls to protect health will be needed as industry develops new techniques, stated Justin M. Andrews, Sc.D., Assistant Surgeon General and associate chief for program, Bureau of State Services of the Public Health Service.

The health implications and dimensions of these techniques must be determined, however, before controls can be instituted, and current practice in the control of communicable diseases, as well as new procedures and indexes, must be carefully examined, Andrews said.

In this connection, Andrews stated that epidemiological evaluation of isolation and quarantine has led to discontinuance of these measures in the control of some diseases and confirmed their usefulness in others.

Epidemiological review of fly control in the prevention of poliomyelitis demonstrated that this disease was apparently spread by contact with infected individuals or with carriers rather than by flies, he said. Epidemiological investigation revealed that malaria was spread by only a few species of mosquito and that control of those species was more

economical than control of all mosquitoes.

Andrews suggested that, in view of the disappearance of cholera and the decline in numbers of typhoid carriers, the coliform index might also be reevaluated epidemiologically.

Bacteriological cultures of rectal swabs from children aged 10 years or less have given immediate and objective results, which are not obtainable from mortality and morbidity data, Andrews stated.

He suggested that this procedure, together with comparisons of the prevalence of carriers in homogeneous populations, might be used by teams of epidemiologists and sanitary engineers in studying the epidemiology and evaluating the control of enteric diseases.

Water and Air Pollution

Other areas in which sanitary engineers and epidemiologists can work together are water and air pollution control, Andrews stated. He stressed chemical and radioactive air pollutants and said that health, physical effectiveness, safety, and comfort will all be affected with increases in population, urbanization, industrialization, and the use of atomic energy.

Little is known about the chronic,

Relocated Lawrence Station Develops New Research

The Lawrence Experiment Station, established in 1886 as part of the Massachusetts State Department of Public Health, has produced a roster of distinguished scientists, teachers, and natural philosophers who have united engineering and biology in the new world of sanitary science.

The station has been a proving ground for students and teachers from New England university engineering departments, including the Massachusetts Institute of Technology, as well as others seeking practical solutions to sewage and industrial waste disposal.

Thus, Clarence I. Sterling, deputy health commissioner of Massachusetts and chief sanitary engineer of the State health department, reviewed the station's contributions to research in public health. Thousands of problems have been tackled by its staff over the years, he said.

The station today is developing a new research program in keeping with its move to a modern building and new site, also, like the old site, along the Merrimack River at Lawrence, Mass., Sterling said. The new site was carefully selected in order that sufficient domestic sewage could be obtained to carry on the research work.

The new buildings house the formerly scattered bacteriological, radiological, biological, water and sewage, and air pollution laboratories. A special research laboratory has been set up to familiarize laboratory personnel with new techniques. A new plumbing research laboratory will train apprentice plumbers and others in the relationship between good plumbing and public health. One branch laboratory is still located at the University of Massachusetts at Amherst in the western part of the State.

Sterling said that the station has appointed a board of research consultants to help solve many of the new problems in sanitary engineering. Board members include the following representatives of the profession:

Harry P. Burden, Tufts College; Rolf Eliassen and Clair N. Sawyer, Massachusetts Institute of Technology; Ralph L. France, University of Massachusetts; Harry G. Hanson, Public Health Service; Charles E. Renn, Johns Hopkins University; Gordon M. Fair, J. Carrell Morris, and Leslie Silverman, Harvard University.

Many New Complexities Challenge Researchers

Pressures of population and technology are rapidly unfolding new challenges to the sanitary engineering profession, according to Assistant Surgeon General Mark D. Hollis, chief engineer of the Public Health Service.

Among environmental forces injecting complications in public health work are the increasing variety and potency of polluting wastes, including those that are radioactive, in all phases of man's environment—air, water, food, shelter, and even space, Hollis pointed out. Methods of detecting, identifying, measuring, and appraising the quality of pollutants, especially in the atmosphere and in water are as yet insufficient to satisfy

needs, he maintained, if controls are to be applied effectively and economically.

Although indicators and classical yardsticks now in use suited the needs of other times, Hollis said, "over-extension in their use by default is no solution to the newer problems. There is increasing evidence, for example, of waterborne virus diseases, yet we have no practicable methods for detecting their presence in water, nor any firm knowledge of the capacity of ordinary treatment facilities to remove them."

From still another angle, Hollis pointed to the failure to capture, reclaim, and put to productive use many wastes that are now being dissipated.

"Even in our own land," he said, "the relative decrease in availability of agricultural resources, such as fixed nitrogen, phosphates, and soil conditioners, has been reflected in notable increases of dollar value placed on fertilizers. It is anticipated that this trend will continue. As the relative abundance of basic resources decreases, the energy and dollar costs of conservation are more readily borne by the community."

Hollis called attention to current processes which recover many valuable materials heretofore regarded as wastes. Drying of sludge, recovering vitamin B₁₂ from sewage, and composts from solid wastes, and conversion of sewage into algal food, he regarded as symptoms of a trend which may be accelerated as population pressures increase.

"The sanitary engineering objective of waste disposal may profitably be shifted to include waste conversion and re-use," Hollis stated. "In a very substantial way sanitation will be facilitated by showing man how he can supply some of his basic demands by re-using what he already has."

He expressed hope that sanitary engineering research may be stimulated by close collaboration of the Robert A. Taft Sanitary Engineering Center with universities and other research resources. In addition to

offering its services to these institutions, the center will focus its attention on development of methods for applying basic knowledge to national and regional problems which individual State institutions and industries find are beyond their jurisdiction or resources.

The center is now exploring methods of bringing its application work into phase with basic research of other institutions.

Lists Planning Objectives For Sanitary Engineers

The World Health Organization estimates that 20 percent of the deaths in the world today are due to faulty environment, stated George O. Pierce, M.S., chief, environmental sanitation branch, Pan American Sanitary Bureau, Washington, D. C.

In many Latin-American countries, enteric diseases are still a leading cause of death, Pierce said, and effective methods of control of some other diseases related to the environment are not yet developed, as in the case of bilharziasis.

A variety of disciplines are needed to solve the many and complex problems of environmental sanitation, Pierce stated. Teamwork will be necessary between sanitary engineers and specialists in the physical, chemical, biological, and social sciences if solutions are to be found now and for problems that will result in the future from advances in technology, he said.

Sanitary engineers must be public health statesmen, Pierce said. They must be able to work with representatives of other governments and with specialists in agriculture, education, industrial production, and communications, and they must endeavor to understand what other people do, how they work, and the legal and other restrictions which apply to their work. In many countries, water supply and waste disposal problems will not be solved until economical, technically sound,

and socially acceptable methods are found, he said.

Planning and Administration

Pierce stated that the most important basic problem in public health is leadership in program planning and administration. He said that the community must be educated to do its part in the planning, and that the support of the medical, nursing, and organized engineering professions must be enlisted.

Plans for community health programs should include the collection of information on population characteristics, vital statistics, health institutions and personnel, governmental structure, voluntary health agencies, social institutions and

customs, economic status of the population, geography, and climate, Pierce said.

In conclusion, Pierce stated that sanitary programs produce economic gains and help to control or to eradicate disease; as a result of improvements in health, a larger number of persons are gainfully employed; the economy expands because of new markets and new sources of labor and materials; and crop yields increase.

Results of changes in environment, he said, can be measured by reduced stream pollution, increase in number of families with safe water supplies, the quantity of available water per person, and other environmental factors.

the test of a readability formula. But in terms of the ultimate objectives, such evaluation assumes that the literature will reach a large proportion of the population for whom it was intended, that it will have some effect in motivating the reader, and that eventually a reduction in mortality will ensue.

According to the authors, what is loosely termed "evaluation" in public health is similar to diagnostic research in clinical medicine. "Evaluation" they restricted to "followup of effect of treatment." In the public health sense, treatment of the community is the institution of certain social actions for specific purposes, such as more clinics.

A Design for Evaluation

In designing evaluation studies, certain fundamentals merit consideration, Greenberg and Mattison said. These they listed as:

1. The need for a clear definition of the target population to be exposed to the program under evaluation.

2. The selection from the target population of a smaller group labeled the "sampled population" for intensive followup of the therapy.

3. The identification of particular subgroups within the sampled population so that individual variations of the program's effectiveness may be pointed out.

4. The division of the sampled population according to some experimental design into two homogeneous groups, experimental and control, and their allocation according to some scheme of randomization.

5. The application of a placebo to the control or comparison group to establish the validity of the evaluation.

Measurements for the two groups are made in accordance with the criteria and at the time agreed on, the authors continued. Comparisons are drawn, and if differences are observed, they are ascribed to the differences in treatment. If the sampled population represents a group of persons smaller in num-

Health Program Evaluation . . .

Not all measures of the effectiveness of a health program require the assistance of experts in statistics and the social sciences, but whatever the yardstick used, it must be handled with precision, in terms of well-defined objectives—according to the papers presented.

List Steps for Designing Evaluation Programs

Evaluation of a public health program should denote a measurement of its effectiveness, stated B. G. Greenberg, Ph.D., professor of biostatistics, University of North Carolina School of Public Health, and Berwyn F. Mattison, M.D., M.P.H., commissioner of health, Erie County Health Department, Buffalo, N. Y. "This effectiveness," they said, "should be measured in terms of the fulfillment of the program's objective."

Preparation of a clear-cut statement of the objectives is the first step in evaluating a program, they said. The person best qualified to state these objectives is the one re-

sponsible for instituting the program.

They said that formulation of the criteria for measuring the successful achievement of the intermediate goal and the design of an experiment or research study to measure precisely the criteria of success previously developed are the ensuing steps.

The ultimate objectives of most health programs, namely, reduction of mortality and morbidity, are too remote to be worthwhile indexes for evaluating a program, the authors continued. Consequently, a multitude of intermediate goals are substituted.

For example, in the preparation of health literature, the literature could be considered by some as having been "evaluated" if it passed

PROGRAM EVALUATION

ber than the target population, then differences between the two study groups might have arisen because of sampling fluctuations.

Tests of statistical significance are usually available to rule out or measure this possibility, they said, but it is inappropriate to use these tests for errors of observation other than those caused by sampling variations since such errors are apt to be much greater in size than the sampling errors.

Every Program Step Needs Evaluation

Even if the term "evaluation" is limited to an appraisal of final program results, the first step in the process must always be an appraisal of the yardsticks used, maintained George James, M.D., M.P.H., and Herman E. Hilleboe, M.D., M.P.H., of the New York State Department of Health.

Dr. James is assistant commissioner for program development and evaluation, and Dr. Hilleboe is commissioner of health.

Of what use, they asked, is a final evaluation if the standards employed are unreliable, invalid, or unnecessary? They consider evaluation more as a scientifically critical point of view which must be built within chronic disease programs during each phase of development than as a special procedure which should be performed periodically.

The validation of the yardsticks forms short-range objectives for the program of the Albany Cardiovascular Health Center. James and Hilleboe stated it is with these yardsticks that planners can build step by step toward the long-range goals. It is in terms of these yardsticks, and only in such terms, that a true evaluation of the long-range goals becomes possible, they declared.

In their opinion, it is unlikely that a scientifically precise evaluation of any existing program for the "control" of adult heart disease could be performed using the yardsticks and

disease classifications now available.

To indicate the types of evaluations which should be performed in the development of a new and complex program, James and Hilleboe presented selected data from the first 1,494 examinations performed at the Albany Cardiovascular Health Center. The center was established in 1953 to provide periodic examination of the cardiovascular status of 2,000 male State employees, aged 40-54 years, in the Albany area.

Medical History

Noting that physicians frequently place great reliance on the medical history of their patients in making a diagnosis, they offered the following data:

"Pain, heaviness, or discomfort in the chest" was the symptom with the greatest relative frequency among patients with coronary heart disease, in comparison with patients with hypertensive heart disease, hypertension, or hemorrhoids. "Aching or tenderness around the heart," "unusually fatigued during day," "feel choked or smothered," and "short wind" were symptoms also associated significantly with coronary heart disease, but "feel heart beating," "heart races," and "ankles swell" occurred about equally in all the diagnostic groups.

Would each competent physician

elicit the same symptoms from the same patient? This is one of the questions, they stated, that must be answered before deciding to rely for screening purposes on the five symptoms which appeared most frequently among coronary heart disease patients.

They found that eight physicians seemed about equal in eliciting the third, fourth, and fifth symptoms given above, but not in eliciting the first and second.

They found, further, that two physicians were responsible for the bulk of the variance for the first symptom and one physician for the second symptom.

Also presented as illustrative of evaluation in terms of short-range objectives were data on the family history of the patients; on the electrocardiogram and the X-ray film as techniques for detecting cardiac enlargement; and on the association of age, obesity, and blood pressure.

Long-Range Objectives

To develop and evaluate measures of the prevalence and incidence of various conditions among the study group, one of the long-range objectives of the program, requires a relatively low refusal rate among this group, James and Hilleboe pointed out. They reported an overall refusal rate among 1,677 State employees of 10.9 percent. The next

Diagnoses made at the Albany Cardiovascular Health Center among 1,394 persons, aged 40-54 years

Disease	Diagnosed at center		Previously known		Newly diagnosed	
	Number	Rate per 1,000	Number	Rate per 1,000	Number	Rate per 1,000
Tuberculosis.....	48	34	26	19	22	16

Diabetes.....	15	11	12	9	3	2
Chronic arthritis.....	22	16	18	13	4	3
Coronary heart disease.....	42	30	30	21	12	9
Hypertensive heart disease.....	42	30	0	0	42	30
Hypertension.....	184	132	62	44	122	88

step, an attempt to assess the extent of heart disease among the refusals, is now being developed, they said.

Concerning prevalence of the various heart diseases in the group, they provided the data in the accompanying table. The diagnostic categories are based upon currently detectable signs and symptoms, they said. In their opinion, these are almost certainly not the best possible yardsticks for this purpose.

Sampling in the Evaluation Of Education Materials

Small, carefully selected population samples can be adequate and can be used to advantage in evaluating health education materials in the process of development, stated Irwin M. Rosenstock, Ph.D., assistant chief, Behavioral Studies, Public Health Service. However, they should be used with caution, particularly in evaluating the actual effectiveness of materials, he warned.

Rosenstock discussed two types of evaluation. One is pretesting while material is being developed to determine the best approach to the subject and to discover any misunderstandings, misinterpretations, or other barriers to successful communication. The second type is evaluation of effectiveness to determine how much a group may have been influenced in the desired direction.

Pretesting

According to Rosenstock, the size of the sample to be used in pretesting depends upon the purpose of the test and the degree of intelligence, amount of education, and experiences of the group from which the sample is selected, the number of population variables relating to possible barriers to understanding, the degree of precision desired in measuring these barriers, and the homogeneity of the group to be reached.

As the heterogeneity of the intended audience increases, he said,

NONFAT DRY MILK IS WHOLE MILK
FROM WHICH BOTH CREAM AND
WATER HAVE BEEN REMOVED

the size of the sample necessary for pretesting also increases, and the more barriers to communication to be identified, the larger the sample needed. Small samples are more likely to be adequate when they are composed of a homogeneous group of persons for whom the educational material is designed.

Among several examples which he cited, Rosenstock reported that pretesting a chart illustrating the relationship between whole milk and nonfat dry milk revealed that women with less than 8 years of schooling did not understand the minus and equals signs. One woman said the chart showed that "after you pour off the cream you have water." Another said that the minus sign showed how far the cream should be taken off the bottle. When the chart was revised, using words and arrows instead of algebraic signs, it was much better understood.

Pretesting a pamphlet recommending the use of salt-soda solution in place of blood plasma showed that most readers misinterpreted the meaning of shock and failed to associate the use of salt-soda solution with the treatment of burns. Several persons said that they would have the injured person drink the solution so that he would not feel shocked when he looked at his injuries, and one woman said that she would drink the solution so that she would not be shocked when she looked at the injured person.

Rosenstock said that any changes made in the material as a result of the initial pretesting must be tested on new groups, but care should be

taken that the meaning of the portions being retested is not altered by presenting them out of the original context.

Evaluating Effectiveness

The use of sampling, in determining the extent to which educational materials achieve their purpose is a much more complex procedure than sampling in pretesting. Selection of the sample and the determination of criteria and measures of effectiveness present difficulties which, Rosenstock said, may require the assistance of experts in statistics and in the social sciences. Pretesting can be learned by public health workers and rarely requires the assistance of experts.

Dental Health Programs Evaluated Objectively

The precise measures of dental caries available today provide the means for continuing objective appraisal of dental health programs, stated George A. Nevitt, D.D.S., M.S.P.H., in a review reemphasizing dental health program evaluation. Dr. Nevitt is regional dental consultant, Region IX office of the Public Health Service, San Francisco.

The appraisal, he specified, is dependent upon periodic age-specific comparisons of dental caries prevalence and tooth mortality. The basic measure is the DMF index, that is, the number of teeth decayed, missing or indicated for extraction, and filled.

Explaining how the DMF index is

used, he pointed out that a decrease in the DMF indicates success, for it shows that the prevalence and incidence of dental caries is being reduced. He noted also that changes in the components may indicate progress even though the total DMF does not change. A decrease in the number of permanent teeth lost would show a reduction in tooth mortality, he said. An increase in the F component would indicate that more needs are being met and therefore that future reductions in tooth mortality might be expected.

Already available or under study, Nevitt remarked, are measures applicable to phases of dental health programs other than dental caries control. He mentioned the graded classification system for measuring fluorosis, or mottled enamel, the PMA index for measuring severity of gingivitis, and the dentofacial index for measuring degrees of malocclusion.

Dental health programs can, in certain instances, be evaluated by subjective appraisal, Nevitt claimed. Whether or not subjective appraisal can be used legitimately, he indicated, is determined by the kind of planning done. For example, he said, when the effectiveness of a procedure such as topical fluoride application has been thoroughly field tested before it is introduced generally, the mere institution of the activity is a sign of progress.

Nevitt called subjective appraisal the most basic, simple evaluation technique available today. It requires no survey, no statistical measure, no clever devices, he said. It requires only a review of the previously prepared plan and the answer to the vital question, "Was this done?"

Acceptable Planning

Because evaluation, of any type, is so dependent upon planning, Nevitt reviewed briefly the requirements of acceptable planning.

1. To accomplish a program objective, both long-range and intermediate goals must be planned.

2. A specific plan listing each intermediate objective should be prepared periodically.

3. Detailed procedural methods must be outlined for accomplishing each intermediate objective.

Measure Gain in Learning In Workshop Tests

Student and faculty opinions regarding a student's contribution to a learning situation should receive greater emphasis, when it comes to grading, than the actual knowledge he gains, according to objective measurements. This finding was indicated in a health education workshop, according to John H. Shaw, Ed.D., professor of health and physical education, Syracuse University, and Andrew S. Coccari, M.A., director of physical education, The Hills School, Huntington, N. Y.

Most of the students enrolled in the workshop were elementary school teachers or nurses. The students were divided into four small groups, each with a full-time instructor. About half the class time was spent in working in these groups; otherwise, the workshop met as one unit.

Attempts were made to evaluate the program statistically:

1. By measurements of the actual increase, or decrease, of knowledge through the use of pretest and post-test forms (A and B) of the Shaw-Troyer Health Education Test, a standard health knowledge test.

2. By determinations of the relationship which exists between peer and instructor ratings of the contribution of individuals to the workshop.

3. By determinations of the relationship which exists between health knowledge and the contribution of an individual to the workshop as measured by student and instructor ratings.

Fifty-nine students took both tests, which were corrected and returned to each one for discussion.

Significant Correlation

The participants were told that the first test was to determine their present knowledge about health. When the second test was administered, they were told that it would measure the groups' gain in knowledge. Students were encouraged to do their best and were assured that the scores would not be used as a basis for grading.

The results of the two tests were assembled and compared as to raw scores and percentile rank.

Total group gain in both scores and percentiles were figured. These results tended to show a fairly consistent increase in the number of correct answers on the second test as compared with the first.

This increase was clearly evident in the 11.1 percent gain in percentile ranking on the second test, as compared with the first test, and the differences between the two scores are statistically significant.

There was an average gain in health knowledge per individual of 3.7 in raw score, and a total gain of 338.

In attempting to determine the relationship which exists between a person's health knowledge and his contribution to the workshop, each instructor, at the end of the sessions, rated his group in accordance with the contribution he thought each member had made. He was also asked to have each student rate all participants in his group.

Although the instructors had a little forewarning that they were to rate students, the students had none. Nor did they have a chance to collaborate in making their judgments. Replies were anonymous.

The mean for each individual in the group was computed, and members were then ranked in terms of their mean score. The product moment correlation of instructor ratings and mean peer ratings was then figured to determine the relationship between peer and instructor ratings of the individual's contribution. This correlation was highly significant, +.82, Shaw and Coccari stated,

and it is on the basis of this finding that they recommend giving greater weight to student and faculty judgments as to an individual's classroom contribution.

By correlating the mean peer ratings and the results of the "before" and "after" tests, the authors found that there is apparently very little relationship between a student's gain in knowledge of health education, as measured by the objective tests, and the rating of his contribution to a learning situation, as measured by staff and fellow members. The correlation of mean peer ratings and scores was $+0.38$ on the pretest and $+0.01$ on the post-test.

Urges Wider Application Of Program Evaluation

More and better applications of the evaluation yardstick to program progress and achievement were advocated by Andie L. Knutson, Ph.D., chief of Behavioral Studies, Public Health Service, and Benjamin Shlimberg, Ph.D., Educational Testing Service, Princeton, N. J.

They described program progress evaluation as the step-by-step assessment of each new phase of a program to keep it headed toward the intended goal. This type of evaluation, they said, yields usable results when they are needed and helps increase the likelihood that the program will be effective.

Program achievement evaluation determines whether or not the goal has been reached, they explained.

The worth of decisions in either type of evaluation, Knutson and Shlimberg pointed out, will depend on asking the right questions and recognizing the significance of relevant variables. This means, they said, differentiating fact from opinion, reliable data from guesswork, and assumptions and hypotheses from firmly established knowledge and principles.

Either type of evaluation can be applied independently of the other, or both may be applied concurrently,

even within the same study, they said.

TV vs. Classroom

They gave us an illustration of dual application an evaluation of the effectiveness of television as a medium for teaching home nursing.

In a study sponsored by the National American Red Cross, one group of women received all their instruction through a series of 13 television programs in Houston, Tex. A second group took the same television course plus an additional hour a week in organized practice sessions; and a third group was instructed by the conventional classroom method, they reported.

A written test and a performance test revealed that all three groups learned about the same amount, regardless of the instruction method, although specific differences occurred. Thus, the evaluation of achievement showed that the teaching of home nursing by television was, in general, as effective as teaching in the classroom, they said.

Further analysis of the test data and inclusion of a questionnaire helped identify difficulties in course content, method, and focus for use in planning future programs and indicated the need of evaluation while a program is in progress, Knutson and Shlimberg reported.

For example, they said, performance test data revealed that more than 40 percent of the women who had taken the classroom course, as well as those in the television-plus-practice group, could not read a clinical thermometer accurately. The TV-only group showed no improvement at all.

This finding, they said, clearly indicated need for further study and correction of this difficulty in planning future courses.

Their data suggested the need for making the practice sessions more effective, if they were to be retained; a change in TV program hours; coverage of the course within a month instead of 7 weeks; and inclusion of a course outline or study guide.

Shows Way To Evaluate State Nutrition Program

A method of evaluating nutrition programs based on the intermediate goal of a wide use of nutritional knowledge was presented by John H. Browe, M.D., M.P.H., bureau of nutrition director in the New York State Department of Health.

Nutrition programs are very difficult to evaluate, according to Browe. Even evaluation such as he advocated is difficult for the New York nutrition bureau, he said, because the nutritionists there have only an indirect relationship with the people they hope to help. A large part of the bureau's work consists of consultations with other professional personnel who provide the actual services.

The bureau's immediate problem was to determine the effectiveness of its existing nutrition programs, Browe said. To find just what the bureau was doing, a review was made of the monthly reports by individual nutritionists and the monthly bureau reports for 1952, the last calendar year completed before the survey. A side result was that the study showed up the weaknesses of the reports and these inadequacies have now been changed.

Classification Shift

The activities in these reports were arranged systematically according to the agencies, organizations, and persons with whom the bureau members worked. It was decided to change this classification by considering the activities in relation to the particular nutritional needs of the different groups of people actually served. For instance, the activity which in the past was recorded as participation in an institute for nursing home operators is now listed in the chronically ill category.

Considering the activity in this manner places it in proper perspective and stimulates thought about goals and objectives, Browe said.

A number of similar categories

have been set up. The first major division was between the well and the sick. The categories for well persons were based on age or physiological state—pregnancy, infancy, early childhood, late childhood, adolescence, adulthood, and old age. The sick are divided into the acutely ill, the chronically ill, the malnourished, and those with particular disabilities such as diabetes, obesity, or heart disease.

Browe expects to have, at the end of 1954, a complete record with sufficient incidental data to know all the bureau's activities for population groups. He hopes to relate this information to the entire need for such activities and, on the basis of this information, to determine the bureau's future program development. This analysis of available data should, in his opinion, provide a solid framework for evaluation on more objective lines.

Program Tested

Browe offered one example of the application of this evaluation technique to an existing program for pregnant women:

The bureau's contact was with public health nurses who taught mothers' classes. Evaluation began by testing the nurses' knowledge of nutrition. Staff education for the nurses was planned by nutritionists on the basis of information gained from the tests. These nutritionists then observed classes taught by the nurses and asked supervising nurses for their opinions of the project. The nutritionists also asked the mothers attending the classes about their knowledge of nutrition. The nurses were asked to observe if any changes in nutritional practices took place in the homes.

Not all types of service offered by the bureau can be evaluated this easily, said Browe.

However, a clear understanding of the purpose of a program is necessary before any evaluation is possible, he continued. There must be a willingness to find out if the purpose has been accomplished. The

selection of an objective criterion is usually possible, he said, and it is upon this modest beginning that the evaluation of any nutrition program must depend.

New Classification Scheme For CV-R Deaths Outlined

An attempt to classify deaths from cardiovascular-renal disease in rubrics said to give both an etiological and an anatomical description of the cause of death was reported by Louis Weiner, Marjorie T. Bellows, Grace H. MacAvoy, and Eli V. Cohen.

Miss Bellows is chief statistician, American Heart Association. Mr. Weiner, Miss MacAvoy, and Mr. Cohen are with the bureau of records and statistics, New York City Health Department; they are, respectively, chief, statistical division; nosologist; and administrative assistant, tabulating division.

The data used in the study were obtained from multiple-cause cards

prepared by the New York City Department of Health early in 1954. They relate to 2,587 certificates on which the underlying cause of death, selected by the conventional rules, was some cardiovascular-renal disease. The authors asserted that etiology and anatomical involvement could be determined for more than 99 percent of the certificates on which at least two cardiovascular-renal conditions were mentioned, and for 80.5 percent of the certificates on which only a single cause was mentioned.

The major changes resulting from the new classification, according to the authors, were (1) an increase in the number of deaths showing hypertensive etiology, and (2) determination of the etiology in more than three-quarters of the deaths ascribed by the International Statistical Classification to cerebral vascular lesions. The proportion of deaths unclassifiable as to etiology was particularly high in the cause-of-death groups involving nephritis.

The Handicapped Child . . .

Itinerant teachers bring the classroom to the home of the blind child; vision screening tests are found to place many in sight-saving classes who do not need it; some institutionalized orthopedic patients go home as a result of a review committee's recheck on status, and some guidelines are offered to help communities help mentally retarded children.

Care of Handicapped Reviewed by New York

Evidence that certain types of handicapped children in the New York City program have been over-institutionalized was presented by five members of the bureau for handicapped children of the New York City Department of Health.

Bureau surveys discovered that the orthopedically handicapped children cared for in hospitals and convalescent homes through the bureau's medical rehabilitation payment program were not receiving the optimum care needed for their treatment and rehabilitation and that they needed more careful and frequent evaluation.

Reporting the study were Helen M. Wallace, M.D., director, Robert S. Siffert, M.D., senior orthopedic consultant, Horace Yu, M.D., orthopedic consultant, Margaret A. Losty, R.N., coordinator of the hospital consultation program, and Helen M. Gossett, acting chief of medical social work, all of the bureau for handicapped children.

Review Committee

Described in detail was one of the remedial steps taken to modify or change the services as the condition and needs of the patients changed. A review committee was formed to recheck primarily the status of all long-term handicapped children provided institutional care by the program.

During the first 6 months, June-December 1953, of the committee's work, records of 210 patients in 20 institutions were reviewed. Of the 10 institutions caring for 180 of the patients, 5 were classified as convalescent institutions and cared for 121 patients.

Inpatient care averaged 575 days per child and the program cost averaged \$4,205 per child. A total of \$883,091 had been authorized.

The review committee recommended the following changes for 100 of the 210 children: 48, return home; 37, screening for admission to special public school classes for cerebral palsied children; 8, transferral from hospitals to a convalescent institution; 2, foster home placement; 2, admission to the State institution for the mentally retarded; 2, transferral from convalescent homes to a hospital; and 1, admission to a residential school for the blind.

The demonstrated value of this approach has led to the review of the records each 6 months, the bureau members said.

Consultation Program

In conjunction with the review activities, they reported, the bureau has developed a hospital consultation program designed to assist the

participating institutions in improving patient care. In addition to better care, they pointed out, the information about the patient and a working knowledge of the institution gained through the consultation program has helped the review committee operate.

The review committee's activities, they believe, may reshape community services for handicapped children. The end result may be fewer inpatient beds in hospitals and convalescent homes, strengthened outpatient services, and more public school classes for children with cerebral palsy and other orthopedic handicaps, they said.

Also likely, they stated, is a re-evaluation of convalescent care—the type of inpatient services the convalescent home should provide and whether alternate services, such as a foster home program and better housing, should be developed.

Would Overhaul Criteria For Sightsaving Classes

Criteria used for the selection of children to be placed in sightsaving classes were disputed on medical grounds and on the basis of experience with 500 or more visually handicapped youngsters by Ralph C. Lanciano, M.D., LL.D., chief ophthalmologist for the Philadelphia Board of Public Education, and an instructor in pediatric ophthalmology at the University of Pennsylvania Graduate School of Medicine.

Lanciano saw no reason for assigning a child with usefully corrected vision to a sightsaving class if he can recognize blackboard writing from a reasonable distance and can read textbook 12-point type without difficulty. He based his opinion on a study of all children examined for admission to sightsaving classes in Philadelphia for the last 9 years.

Many State and city regulations governing the placement of visually

handicapped children, he said, are outmoded. The criteria established by these regulations are impractical and unrealistic by modern ophthalmological standards, he continued.

Modern Concept

Lanciano objected to the method of relying on a child's recognition of test types on the Snellen chart to determine his power of vision. The child's response, according to Lanciano, depends on a number of factors in addition to his visual acuity. His power of attention, his willingness to cooperate, and his reading ability must be taken into account. It is also necessary, Lanciano said, to consider the competence of the child's nervous system to transmit images from the eye to the visual area in the brain.

The regulations of two States, New York and Ohio, recommend special classes for children who, after correction, are unable to read 5-point type, said Lanciano. But elementary and high school textbooks are rarely, if ever, printed in a type less than 12-point, according to Lanciano. He considers children visually handicapped if adequate correction doesn't enable them to read 10-point type.

Lanciano also disagrees with those regulations which call for special treatment of children if they have 20/70 corrected vision in the better eye. A child with this defect, he said, doesn't recognize images less than 1½ inches high from a distance of 20 feet. Legible blackboard writing, he continued, doesn't include letters smaller than 1½ inches in height, and modern classrooms can solve the problem by seating adjustments.

The idea behind many of these regulations, said Lanciano, is that sightsaving classes can retard, arrest, or ameliorate the pathological processes. He claimed, however, the greater majority of the clinical entities noted in children attending these classes are determined by heredity or by degenerative, con-

genital, or maldevelopmental processes, none of which are subject to environmental control.

The decision to place a child in sightsaving classes should not be based on the degree of visual loss or on a clinical label, said the speaker. Instead one should determine how much visual function remains and what the child can do with it in terms of the curricular demands of regular education.

Community Planning Urged For Mentally Retarded

Comprehensive planning by the community to deal with the problem of mental retardation, with leadership provided by public health workers, was urged by Joseph Wortis, M.D., director of pediatric psychiatry, Jewish Hospital of Brooklyn.

Public health workers can be especially useful by sharing with parent groups the modern scientific knowledge needed to cope with the problem, he said, pointing out that parent groups tend to become focal points of activity in this field.

Although institutions for the care of severely retarded persons will continue to be needed, the future development of work in this field demands increased attention to the encouragement of community facilities, Wortis said. Institutions, he added, should aim to return as many children as possible, as soon as possible, back to the community.

He reported that an estimated 60 to 80 percent of the patients of the Jewish Hospital's retardation clinic could, under favorable circumstances, perform socially useful work in a supervised setting. During recent years, he stated, institutionalization has been recommended for only 24 percent of the children seen at the clinic. The figure would have been lower if suitable family or community arrangements had been available, he maintained.

Recommended Approach

Stressing the need for close integration of educational, recreational, medical, and vocational services for the mentally retarded, Wortis made the following general suggestions:

1. Appropriate schooling should be provided for all retarded children, except the very few incapable of learning.
2. Many mildly retarded children, especially the large number who can be described as educationally underprivileged, will do much better in classes with normal children than segregated, if the classes are small enough to allow teachers to give them the consideration they need.
3. Classes for the more retarded should be even smaller.
4. Special schooling need not be limited to ordinary academic training.
5. All-day schools should be made available to children needing care and supervision which their families cannot provide.
6. Diagnostic and rehabilitation clinics must be more widely established, preferably in a hospital setting where teams of workers may study the children and assist in their rehabilitation.
7. Distressed and overburdened families need the enlightened help of social agencies.
8. Vocational training and vocational placement under suitable safeguards must be provided for the older children.

Scope of the Problem

Wortis estimated that 3 percent of the children in this country, about 700,000 of the children attending school today, are likely to require special educational help because of mental retardation. However, only about 115,000 children are attending special educational facilities, he said, stressing the difficulty of making any statistical estimate of the scope of the problem because of the lack of reliable data and the wide variation in definitions of terms.

The uncritical use of mental tests

has served to perpetuate some misconceptions concerning the nature of mental retardation, particularly mild retardation, Wortis declared. Since all mental tests are tests of performance and performance is the result of both innate capacity and previous training, he said, it can be seen why socially deprived persons, who tend to score low on the tests, have often been falsely regarded as biologically defective.

On the other hand, Wortis continued, there are many persons whose biological deficiencies are not given the special consideration they demand. He mentioned mongoloids as one group and indicated that many mongoloids could benefit from family life and from special training in their own communities.

Lists Education Trends For Blind Youngsters

How are present educational trends enriching the lives of blind children? What of the future of these children?

Three basic, but greatly varying, patterns are followed in the education of blind children, Georgie Lee Abel, M.A., consultant in education, American Foundation for the Blind, New York City, said, in discussing the gains being made toward the effective functioning of the future blind adult.

The newest is the itinerant plan, which makes it possible for an occasional blind child to remain in his own school district and have necessary services brought to him by qualified teachers or consultants, Abel explained. This system is found where there are not enough pupils to justify the expense of a teacher and a specialized program. Where it is constructively set up, it works well for older children, she continued.

Education in a residential school for the blind and specialized programs or braille classes in the public schools are the other typical pat-

terns, Abel said. The former is recognizing the significance of more constructive home and school relations for the isolated child. The latter is turning into the "resource room" where the blind child is enrolled in the regular class and returns to the specialist teacher for help when necessary. The resource teacher is available to other teachers who have blind children in their classes. She prepares comparable text and reference materials in braille for the blind children, actually teaches them certain skills, and counsels their needs.

Gains of the Present

In listing some of the professional gains, Abel said that the future should seek to free blind individuals from many of the past prejudices of their sighted friends who still find it difficult to react with respect and understanding. Her list included these main points:

1. The establishment of more pre-school programs for blind children represents perhaps the greatest single step in more effective educational planning in their behalf.
2. The greatest contribution of the present can be found in the parents, who, when given sufficient help as soon as needed, are showing that they are capable of accepting and understanding their children.
3. Important sociological and psychological research has been most productive, as to parent-child relations, adjustment to blindness, emotional needs of blind children, and so forth.
4. Teacher preparation facilities are improving; teachers are showing a capacity to accept the responsibility for planning constructive courses.
5. More cooperative planning is being accomplished at the State level in the interest of screening, case finding, and evaluation of the most effective placement.
6. General health and welfare agencies are expressing an increased desire to serve blind children and their families.
7. Through the process of study, action, and practice, carefully de-

veloped legislation is being achieved which will affect and aid blind as well as other handicapped children.

Offers Checklist as Aid To Program Planning

A checklist to help a community organization evaluate its position in the community and to determine its offering toward a proposed program was presented by Louis Speker, M.D., M.P.H., director of the bureau of maternal and child hygiene, Connecticut State Department of Health, during his discussion of ways to get maximum use of available community resources in giving aid to children with orthopedic conditions.

Some of the items to be evaluated for a program include purpose and objectives, types of services needed, standards for the conditions to be served, geographic area, estimated number of persons to be served, source of funds and budget, personnel needed, personnel available, and

additional personnel to be recruited.

With a clear picture of the facilities available and of the program to be superimposed, the community may develop the program for the handicapped children upon a set of major principles which Speker itemized:

1. Base planning upon the knowledge of the extent and nature of the problem.
2. Define the program and its limitations.
3. Set up a list of priorities.
4. Integrate the special services with overall health services.
5. Focus the program on the individuals for whom it is provided.
6. Give the local community a chance to assume as much responsibility for providing services as is possible.
7. Secure professional leadership to assure a high quality of services.
8. Provide for demonstrations and evaluations.
9. Encourage and make an opportunity for individuals and groups to participate.
10. Briefly and clearly put the plan in writing.

Amebiasis, Infantile Diarrhea . . .

Two amebicides are found effective in an Indiana outbreak; resuscitating equipment in a hospital is linked to the spread of diarrhea among the newborn; a fluorescein derivative opens the way to a possible new method of diagnosing amebic dysentery; and two reports are made on the potentially pathogenic characteristics of Escherichia coli O111.

Amebic Dysentery Work Gets a Green Light

The diagnosis of amebic dysentery by means of fluorescent antibodies is promising although the method remains to be perfected, according to a report made by Morris Goldman, Sc.D., director of the Intestinal Para-

sitology Laboratory at the Communicable Disease Center, Public Health Service.

Amebic dysentery is difficult to diagnose in any temperature climate, he continued, since the classic picture is rarely present, either clinically or parasitologically. In many cases, it is difficult to distinguish the

causative organism of the disease, *Endamoeba histolytica*, from a harmless organism commonly found in the intestinal tract of man, *Endamoeba coli*. The parasitology laboratory is particularly interested in developing objective criteria for differentiating the two organisms.

Recent Development

The staining of antigen with antibodies tagged with fluorescein is a development based on the work of Coones and Kaplan in 1950. Antiserum for the antigen under investigation is obtained in the usual manner and is tagged with a fluorescein derivative. An antigen-antibody reaction is then produced. The product of this reaction can be seen in minute quantities because it emits a green fluorescence when exposed to ultraviolet light.

The fluorescence can be detected easily against the dark background with an ordinary microscope fitted with appropriate filters and illuminated with intense ultraviolet light, Goldman said.

Application of this method to the identification of cultures of *E. histolytica* and *E. coli* was described in recent papers by Goldman. In these he indicated that when cultured individuals of the two intestinal *Endamoeba* were mixed in a single tube, the fluorescent antibody method made it possible to distinguish the organism which causes amebic dysentery from the harmless parasite.

Latest Studies

In the present paper, Goldman presented preliminary results obtained in the last few months. All previous work had been done with two species of amebae—the harmless and the harmful—grown in separate culture media and maintained in this way for a long time—in some cases for many years.

The present research was aimed at determining if the same results could be obtained with newly started cultures of amebae taken directly from the intestinal tract where, per-

haps, the two species had been living together.

Accordingly, a collection of fresh stool samples was made. Those showing *Endamoeba* trophozoites or cysts were inoculated into culture media. Of 30 cultures inoculated, 11 were considered suitable for staining with fluorescent antibody to *E. histolytica* and *E. coli* within 3 days. An additional culture was stained one week after inoculation.

Emphasizing the practical importance of this experiment, Goldman found that it was possible to work with newly started cultures. In fact, he continued, the 48- and 72-hour cultures of the original inoculum frequently showed more amebae than later transfers. This did not mean, he added, that distinctions between the two types of freshly isolated amebae were always clearcut or easy to make. Though the results are encouraging, Goldman pointed out that there are indications of strain differences and that amebae of one species did not fluoresce to the same degree in different cultures. He said the test tube methods are too cumbersome and that work is progressing on staining smears.

The fluorescent antibody method of diagnosing intestinal amebae is not expected to replace other diagnostic procedures, he said. But he hopes that the method will become another valuable tool in the hands of parasitologists and technicians.

Believe Infantile Diarrhea Has One Etiological Agent

Recent evidence indicating that *Escherichia coli* O111 is the sole pathogenic agent of acute infantile diarrhea was said to be reinforced by the study of an outbreak of the disease at the U. S. Army Hospital in Fort Belvoir, Va.

The study was reported by Lt. Col. Robert B. Lindberg, MSC, USA, Viola M. Young, Ph.D., bacteriologist, and Joel Warren, Ph.D., chief,

all of the department of bacteriology, Army Medical Service Graduate School, Walter Reed Army Medical Center, and by Capt. W. D. Belnap, MC, USA, chief, pediatrics section, Fort Belvoir Station Hospital.

A total of 51 cases were hospitalized at Ft. Belvoir during the epidemic which reached its peak in December 1953 and virtually disappeared in February 1954, according to Lindberg and his associates. Patients under 1 year of age comprised 94.1 percent of the cases.

The epidemic, they said, was typical in its failure to affect breast-fed infants or to cause serious illness among older children. The overall mortality rate for the hospitalized cases was 15.7 percent, but for babies 28 days old or younger, it was 40 percent.

Unknown Virus

The causal relationship of *E. coli* O111 to epidemic diarrhea of the newborn has been established in previous research, Lindberg and his co-workers continued, but the existence of an unknown virus as a concomitant etiological agent has often been suggested, and previous studies haven't eliminated that possibility.

In the present study stool and vomitus specimens of infants in an acute phase of the disease were subjected to laboratory examinations. *E. coli* O111 was recovered, often in virtually pure culture, from 90 percent of the cases cultured. The organism was also recovered, though infrequently, from adult carriers and contacts. Emphasis was placed on newer test techniques including tissue cultures, they said, but no viral agents were recovered.

Although they pointed out that negative results can never, in a sense, be absolute, Lindberg and his colleagues felt that their series of negative isolation attempts strengthen the idea that *E. coli* O111 may act as the sole etiological agent of infantile diarrhea.

The bacteriological aspects of the study resembled descriptions of other

epidemics—patients did not respond well to antibiotics. Considering recently reported success with neomycin, the drug of choice here, they said, may be only approximately indicated by *in vitro* tests.

The report went on to make the following points:

A low titer but significant agglutinin rise to *E. coli* O111 was shown in convalescent serums of 85 percent of patients examined, in contrast to earlier observations of absence of serologic response in this condition.

Cultural reactions of 87 strains showed small but significant numbers of strains varying from the basic pattern of delayed sucrose, salicin, and sorbitol fermentation. Eighty-three percent of the strains were hemolytic.

Indication of heightened toxicity for mice was obtained.

Schwartzman reactions, both systemic and cutaneous, were carried out, and a heightened tissue sensitizing and reacting potential was demonstrated for the O111 strains over those of control strains of *E. coli*. The possibility is present that absorption of sensitizing antigen with subsequent contact with the coliform strains may suffice to set up the fatal hemorrhagic reaction in infants.

Colorado Study Indicts 4 *Escherichia Coli* Types

The isolation of 4 colitypes—*Escherichia coli* O111, O55, O73, and O86—from infant diarrhea cases in Denver supports the theory that *E. coli* is causing infantile diarrhea, according to Maj. C. D. Graber, M.S., bacteriologist at Fitzsimons Army Hospital, Denver.

In all, 128 diarrhea cases were found among 538 pediatric and nursery cases studied in Denver hospitals during 1952 and 1953. Of significance, Graber said, was the fact that no suspect *coli* pathogens were recovered from the normal stools of the remaining 410 children.

Graber told how the yearly out-

breaks of enteric disease in Colorado led to a search for the suspect organism. A 15-month study was undertaken in Denver to determine the occurrence of possible pathogenic *coli* in all pediatric admissions, regardless of diarrhea.

The Study

The study started with 33 cultures from diarrheas at Colorado General Hospital. These had been saved for typing, Graber explained. Most of the other cultures represented unselected sampling, he said.

At Fitzsimons and Colorado General, cultures were procured at intervals from all patients without regard to illness, he continued. At Children's Hospital and the Florence Crittenton Home, specimens were taken on all frank cases of diarrhea. Cultures were obtained by rectal swabs and examined for nonlactose fermenting enteric pathogens and suspect colitypes.

Although the rectal swab technique is excellent for *Shigella* work, Graber feels that the method fails to reach the most favorable fecal areas and that this may account for the low incidence of pathogenic colitypes he encountered.

Salmonella paratyphi, *Shigella flexneri* 3, and *Shigella sonnei* 1, Graber said, were the only established enteric pathogens isolated from the diarrhea cases, which were of more than mild character. The 4 colitypes were cultured from 4 diarrhea specimens, he continued. All were from male cases, and all except the O73 came from children under 1 year.

Incriminate Resuscitators in Salmonellosis Spread

Diarrhea epidemics among newborn infants can in some instances result from infections spread by the resuscitators used to administer oxygen and carbon dioxide and to apply artificial suction to the babies, said A. Daniel Rubenstein, M.D., M.P.H.,

director of the division of hospitals, Massachusetts Department of Public Health, and associate clinical professor of epidemiology, Harvard School of Public Health.

Rubenstein also stated that, contrary to generally accepted opinion, some types of infectious diarrhea contracted in hospitals can be transmitted from infants to older children and adults at home. However, the resulting illness, which may be serious for the newborn, is only rarely noticeable, and then in a mild subclinical form, among household contacts. This indicates a marked susceptibility of newborn infants to organisms that are relatively harmless to older children and adults—a fact which must constantly be remembered, Rubenstein warned.

He reported the findings in two outbreaks of infectious diarrhea caused by *Salmonella* organisms. The resuscitator was considered a source of infection after an epidemic of salmonellosis persisted in one hospital despite a quarantine of sick infants and the sterilization of every other piece of obstetrical and nursery equipment. Tests by the diagnostic laboratory of the Massachusetts Department of Public Health isolated *Salmonella montevideo* from the water trap of the resuscitator. The same species had previously been recovered from infants affected by the disease, Rubenstein said.

Polluted Air

An examination of the resuscitator showed that no provision had been made to prevent a contaminant in the water trap from escaping into the atmosphere with an exhausted from the apparatus. This made it apparent, Rubenstein continued, that contamination of the fluid in the trap had resulted in a spray of *Salmonella* organisms into the atmosphere of the delivery room when the resuscitator was being used for suction.

An outbreak of salmonellosis at the second hospital also appeared to result from a contaminated resus-

citator. Another species, *Salmonella barclay*, was recovered in pure culture from the machine's water trap and also from sick infants.

Two factors associated with the epidemics made it probable, said Rubenstein, that the resuscitators were responsible. In both hospitals, the incidence of illness among exposed infants was high—52 percent in the first and 82 percent in the second. This suggested widespread distribution of the infectious agent. In both outbreaks, the interval between birth and the onset of illness was short enough to indicate that infection might have occurred at delivery or a short time later.

Steps Taken

A series of cultures taken by the State health department in the course of regular hospital inspections showed that contamination of resuscitator water trap fluid was not infrequent. Quantitative analyses of organisms isolated by cultures often resulted in very high bacterial counts, according to Rubenstein. Since delivery room supervisors were completely unaware of danger from this source, the water traps were sometimes washed after use but seldom sterilized. Rubenstein said that the problem has been brought to the attention of manufacturers of resuscitating equipment.

Bacteriological study of resuscitators also revealed frequent contamination of catheters and face masks. Rubenstein suggested that this finding indicated a need for greater care on the part of delivery room supervisors and hospital administrators.

Amebacides Pass Test In Indiana Outbreak

Two amebacides, oxytetracycline and fumagillin, were found equally effective when tested under ideal conditions during a 1953 epidemic of amebiasis in South Bend, Ind.

Reporting this result were Robert

W. Sappenfield, M.D., instructor in the departments of preventive medicine, public health, and pediatrics, Louisiana State University School of Medicine, William M. Frye, Ph.D., M.D., professor of tropical medicine and dean of the same institution, F. R. N. Carter, M.D., South Bend city health officer, Carl Culbertson, M.D., acting director of the South Bend Medical Foundation, and two members of the Public Health Service Communicable Disease Center staff, Marion M. Brooke, Sc.D., chief of Parasitology and Mycology Section, and F. M. Payne, M.D., epidemic intelligence service officer, Enteric Disease Laboratory.

The outbreak of amebiasis, probably caused by the contamination of a private well, affected more than 800 employees of a woodworking plant, they reported. To avoid further spread of infection, the plant's source of water was changed to the municipal system before the scientists began their study.

The large number of people involved and the removal of the primary source of infection made the situation ideal for testing purposes. Previous evaluations, they said, were retarded by the necessity of treating a small number of people at one time or, if the groups were large, by the continued possibility of heavy, prolonged exposure to infections in such places as mental institutions and prisoner of war camps.

Sappenfield and his associates said that another ideal test condition was the apparent widespread infection with the same strains of *Endamoeba histolytica*. The organism had caused death and severe illness as well as asymptomatic infections among persons affected by the epidemic.

Drugs Used

Oxytetracycline, they reported, was shown by Frye and his co-workers in Korea to be the most effective single agent then in use for the treatment of amebic dysentery. It was chosen for the present study to confirm its effectiveness on a

great number of asymptomatic cases and also because conditions in South Bend permitted a longer followup period than was feasible in Korea.

Fumagillin was previously tested in the laboratory and on small groups of patients, they said. The present research project was its first comparison on a large scale with an agent known to be useful against amebic dysentery.

Of the 1,561 plant employees involved, 1,542 contributed specimens for examination and 52.4 percent were found to be harboring *E. histolytica*.

A checkup made 3 to 4 months after the drugs had been evenly distributed among the test group showed that *E. histolytica* had disappeared from the gastrointestinal tracts of 94.4 percent of those who had received oxytetracycline. Fumagillin, they reported, gave similar results in 93.8 percent of the patients treated. No evaluation of therapy for extra-intestinal amebiasis could be made. The number of patients who complained of reactions to therapy was approximately the same with both drugs, the research group reported. For the most part, they said, these complaints were mild and disappeared when treatment was completed.

Trace Amebiasis Outbreaks To Factory's Wells

Chlorination of drinking water won't prevent disease outbreaks if badly constructed or located wells are contaminated by nearby sewers, according to three members of the Indiana State Board of Health who reported tracing a 1953 amebiasis outbreak to a chlorinated well water supply in a South Bend factory.

The project was discussed by Andrew C. Offutt, M.D., State health commissioner, B. A. Poole, B.S.C.E., director, bureau of environmental sanitation, and George G. Fassnacht, M.C.E., chief, water supply section.

Amebiasis, they explained, is used as a general term for all *Endamoeba histolytica* infections including amebic dysentery and related but less serious conditions. Waterborne amebiasis epidemics are rare in this country, they said, and acceptable chlorination procedures are sufficient protection against fairly common bacillary dysentery and coliform organisms but have no effect on *E. histolytica* cysts.

When Offutt and his associates found that 31 of 46 amebiasis cases in the South Bend area occurred among 1,500 employees of one factory, they concentrated their study on the plant. A sample survey of approximately 10 percent of the employees showed that a little more than half were harboring *E. histolytica*. Contamination of water and milk supplies at the employees' homes and of food served at the factory was ruled out by extensive investigation, Poole and his co-workers reported. They examined other possible sources of infection but obtained no significant data.

Dye Test Used

Thus by exclusion, they said, the most probable cause of this outbreak was contamination of the plant's private water supply. The contamination was clearly shown, they reported, when dye placed in a sewer for experimental purposes appeared in the well water. Examination of the well apparatus, made as a result of the dye test, uncovered leakage in a pipe between the vertical turbine pump and a receiving tank into which the pump discharged well water under atmospheric pressure. The pipe was only five horizontal inches from the sewer, said Offutt and his group.

Unusual Epidemic

Characteristic outbreaks of amebiasis, they said, are explosive in nature, affect a relatively large percentage of the exposed population, and are preceded by abnormal diarrheas if the major infection is one

with more severe symptoms. The South Bend epidemic, however, was sporadic, confined, and often mild.

Although cases appeared as early as 1950, Offutt and his associates said their final tabulation shows there were never more than 1 to 3 new cases in any 1 week and only 22 cases during the 15-week period in 1953 when the epidemic was at its height. Clinical symptoms of amebic dysentery didn't always appear in infected individuals, they reported, but said that a majority of the cases

under study were characterized by bowel movements numbering from six a day to fecal incontinence.

The outbreak was obscure in its early phases and there was a lack of immediate correlation between health department reports and the actual date of onset in many cases, said the Offutt group. As a result the existing epidemiological evidence was misleading and a retrospective study became necessary when the epidemic was recognized in June 1952.

Planning and Administration . . .

Undergoing constant reassessment is the extensive range of basic services provided by local and State health departments. Some of the refinements in program administration that have been developed are reported here.

Sanitation Programs Need Reappraisal

Local sanitation programs today are not being directed to the more serious health problems, according to Charles C. Spencer, M.C.E., director of the division of environmental sanitation, Erie County (N. Y.) Health Department.

In Spencer's opinion most such programs are still directed toward control of gastrointestinal diseases, which are now negligible in the United States, in spite of the fact that respiratory diseases make up a large proportion of the communicable diseases today. Home accidents require more attention, though it is difficult to define the usefulness of environmental measures to prevent them, he said.

Cooperative Planning

To best contribute to the long-term development of an area, public health

engineers in health departments must work very closely with local officials, and particularly with planning boards, Spencer declared. Although enforcement activities should not be neglected, time devoted to encouragement and development of communitywide sewer and water facilities or to the stimulation of voluntary housing improvement programs should be more valuable and productive in the long run, he added.

Sanitation workers in health departments as well as sanitary engineers must participate in community planning and design if their objectives are to be accomplished, Spencer continued.

"Ideally, one man should cover all aspects of sanitation in a limited district," he said, for by so doing "he becomes more familiar with local officials and with the needs and customs of a particular neighborhood which influence all aspects of sanitation. However, from a point of view of ad-

ministration and program direction, specialization in certain aspects of the work appears to be desirable."

The size of a staff should be based on density of population and the type and extent of the problems in an area rather than on the total population, Spencer stated.

Public demand for the services of a sanitation division is increasing, and although some of the community's problems are not always of immediate public health importance, the sanitation division is the only public agency organized to deal with them. On that basis, he purposes, that for administrative reasons it is probably well for the sanitation division to assign needed personnel to the health department. However, he cautioned, there should be an awareness of real public need as contrasted with public demand.

Nurse Services Evaluated By New Record System

The mark sense system of reporting and tabulating nursing activities in the Erie County (N. Y.) Department of Health serves as an index of problem situations, according to Mary E. Jones, M.S., the department's assistant director of public health nursing.

The system, installed in 1951, is used to plan and evaluate programs, to adapt nursing services to community needs, and to supervise nursing performance, Jones stated. It has reduced the amount of nursing time spent on clerical work. About 10 to 12 thousand cards are handled monthly.

The new system is now being used for a 4-year study of a community by nursing area, Jones said. Data were collected on birth and death rates, population shifts, health services utilized, type of nursing service, and nurse performance. Analysis has brought about a concentrated effort on individual nursing contacts in certain census tracts. The study has served to emphasize services for pre-school children, too.

Eventually, each nursing district will have similar information in looseleaf form, which will be kept up to date, she added.

The objective data collected makes it possible for the nursing supervisor to anticipate workloads, Jones continued. It has helped justify the demand for increased bedside nursing in one rural district, she said. Statistical tabulation of reports on nursing visits has produced a baseline of performance for the average nurse within each district, as well as baselines for field visits and school and clinic visits, she said. These are only quantitative, she cautioned, and must be used with other pertinent factors for evaluation.

The system operates as follows, Jones said:

The nurse checks the information concerning the specific activity performed on an individual card for statistical use. With the addition of the nursing notes pertaining to the content of the activity, a duplicate card becomes the service record.

All districts use the same card for reporting, punched by nurse number and card number before distribution.

After mechanical tabulation of the statistical cards, a report is available, monthly and quarterly, for each nursing district. It is tabulated on an administrative basis and on a service basis.

On an administrative basis, it shows the work performed by all nurses for a particular district office regardless of the district in which the service occurs.

On a service basis, it shows the amount of nursing work performed in a given district by any nurse.

Detroit Cites Advantages Of Centralized System

Continuity of patient care and administrative economy and efficiency mark Detroit's centralization of all municipal health functions within the health department, according to

Joseph G. Molner, M.D., M.P.H., and Vlado A. Getting, M.D., Dr.P.H.

Detroit's gradual consolidation of health functions is contrary to what they see as the prevailing trend of assigning health activities to several agencies.

Dr. Molner is commissioner of the Detroit Department of Health and professor of preventive medicine, Wayne Medical School, and Dr. Getting is professor of public health practices, University of Michigan School of Public Health.

In addition to the usual public health activities, they reported, the Detroit Department of Health administers the three city hospitals operated for the care of the needy sick and for emergency cases—the Herman Kiefer Hospital, containing the new 250-bed tuberculosis unit, and the contagious disease and maternity units; the Maybury Sanatorium for the tuberculous; and, since 1949, the 538-bed Receiving Hospital, and its 48-bed emergency branch, containing the general, psychiatric, and emergency units.

The consequent integration of hospital and medical home care for the indigent with the preventive program of public health is profitable to the city at large, the immediate recipients, the city officials, the practitioners, and the health department staff, Molner and Getting declared.

Continuity of Care

As an example of program continuity, they cited tuberculosis control. The health department tuberculosis coordinator, they explained, is concerned with the entire program—case finding, health education, sanatorium admission, care, and discharge, and followup of the patient after discharge.

Prompt hospitalization of newly discovered cases, rapid examination of contacts in the hospital clinics, ease of transfer from the Maybury Sanatorium to the Herman Kiefer Hospital for surgery and back according to the patient's needs, earlier return home for continued anti-

microbial treatment when suitable, and periodic reevaluation in the outpatient clinic by the same agency—these were given as advantages accruing from undivided authority.

In addition to the secondary prevention measures of early detection and health education, Molner and Getting said, the Detroit Department of Health can practice primary prevention through BCG vaccination of newborn infants arriving at the maternity unit and by followup in the well child conference and in the tuberculosis outpatient clinic. These prevention measures reach a medically indigent group in which tuberculosis is more prevalent than in other groups in the city, they said.

Among the administrative advantages, they said, are the uniformity of personnel policies and records for the public hospitals and health divisions, pooled purchase of supplies, and centralized ambulance and similar services.

The potential problem in the division of the health officer's time between hospital administration and public health practice is minimized by the employment of administrative specialists, Molner and Getting indicated.

Cautions Against Transfer Of Sanitation Inspections

The sanitation inspection program is a health department function and its transfer to other municipal agencies is at the jeopardy of health protection, the Committee on Municipal Public Health Engineering stated in its report.

Presenting the report was P. W. Purdom, director of environmental sanitation, Philadelphia Department of Public Health.

Improved administration of sanitation inspection programs can be achieved through better use of trained personnel within the health department and through the development and acceptance of reciprocity

of inspections between health jurisdictions, the report stated.

The committee considered three problems in the administration of local health department sanitation inspection programs: transfer to central agencies outside the health department; generalization versus specialization within the health department; and overlapping inspections between health jurisdictions.

The report, in summary, stated the following:

Transfer of sanitation programs from health to other departments may result in loss of effectiveness in protecting public health.

Actually, consolidation of inspection activities does not take place when a central inspection agency is established because of technical complexities.

Sanitation programs function most efficiently and effectively under professional supervision charged with the primary responsibility to protect the public health.

Generalization of sanitation personnel within the health department can be utilized to a greater extent than previously practiced. Thus reduction of annoying duplication and improved efficiency of operation can be obtained.

Development of reciprocal inspection programs between health jurisdictions in an area where duplication of effort can be eliminated without hindering public health objectives. This deserves further study and implementation.

The Sanitary Engineer In Public Works

How sanitary engineers in health departments contribute to the conception, design, improvement, and operation of public works in municipalities was described by Harold Romer, chief, division of waste disposal and pollution control, New York City, and Rolf Ellassen, professor of sanitary engineering, Massachusetts Institute of Technology.

Aroused by failures of home sewage systems installed since 1946, the New York City Department of Health in 1952 took over active supervision of home sewage disposal installations through an interdepartmental committee.

Another example of interdepartmental action described related to the special board created at the suggestion of the health department in 1943 to protect the public water supply of New York City.

The economies of large-scale operation of sewage treatment plants suggested further opportunities for health departments to require essential hydrographic studies and biochemical assays prior to approval of plans.

Brookline, Mass., was cited as an example of a municipality where public health engineering, backed by inspection and police powers of the health department, succeeded in improving waste disposal operations involving an incinerator and a land-fill.

In relation to the budget, Romer and Ellassen stressed that the engineers of the health department can be particularly helpful to other departments in demonstrating and justifying the need for funds adequate to employ trained personnel, to conduct studies essential to economical operations, to provide an adequate maintenance staff, and to operate important control devices.

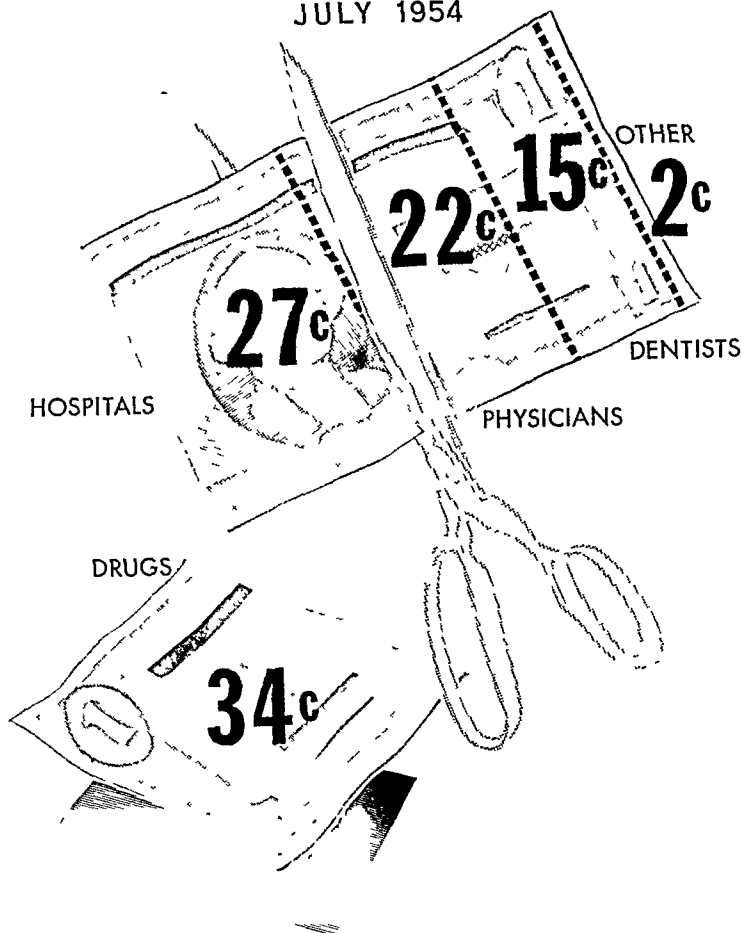

They cited a common condition: lack of funds for maintenance of devices that prevent sewer overflow. Raw sewage then passes the obstructed control gates; the waters are polluted, and the greater part of the investment in the treatment plant is wasted.

Rhode Island Stresses Basic Low Cost Care

Rhode Island emphasizes minimum adequate medical care for its public assistance recipients, according to P. Joseph Pesare, M.D., Dr.P.H., medical director, and John T. Tierney,

The Medical Care Dollar

RHODE ISLAND PUBLIC ASSISTANCE
JULY 1954

medical social work supervisor of the office of medical service, Rhode Island Department of Social Welfare.

In July 1954, a total of 31,240 public assistance recipients, 3.9 percent of the 1950 State population, were receiving medical care at an annual expenditure of about \$1,300,000, Pesare and Tierney reported.

They explained that the medical care program is financed from a "pooled fund" made up by drawing from assistance funds a monthly amount for each assistance recipient. Federal participation in this pooled fund amounts to about 25 percent, they said. The monthly assessments per person or case in the Federally

aided categories are: old-age assistance, \$5; aid to dependent children, \$7; aid to the blind, \$6; and aid to the disabled, \$9. The State public assistance office pays the sources of services and supplies directly from the fund, they explained.

Minimum Adequate Care

Under the heading of "adequate" care, they said, is an extensive range of basic services and supplies provided within the framework of conditions set down by the department.

Listed were the services of private physicians, medical consultants, dentists, osteopaths, optometrists, opticians, and chiropodists, and diagnostic X-ray and X-ray and radium

therapy, clinical laboratory services, surgical and prosthetic appliances, ambulance services, prescribed drugs provided by pharmacists, hospitalization, clinic care, convalescent and nursing home care, and home nursing services.

Under the "minimum" heading, they said, Rhode Island insists on public assistance that supplements personal and community resources, but does not supplant them. They also pointed out that the program does not provide luxury-type medical services to the patient and that special approval is required for extraordinary or expensive services and supplies.

For example, they stated, dentures cannot be authorized without consideration of the age of the patient, length of time the patient has been without dentures, condition of present dentures, and patient's attitude.

During one 30-week period, Pesare and Tierney reported, the total amount requested for dental care for adults in the Federally aided program was \$69,172. After review by the department's dental consultants, about 52 percent was approved, 33 percent denied, and 15 percent left pending for future consideration.

Practitioner's fees paid by the State are lower than those expected of average income people who are paying for their own services, they said. The physician receives a maximum of \$7 for a home visit and \$9 for a boarding, nursing, or convalescent home visit regardless of the number of patients seen. The maximum all-inclusive rate for hospitalization is \$14 a day.

Moderate Control

Moderate administrative controls are used, they reported. Bills are accepted without prior authorization for physicians' visits up to 8 a month for an acute illness and 2 a month for a chronic illness. However, they said, all dental services, except for the immediate relief of pain, require written authorization.

Pesare and Tierney reported that the same medical care standards prevail throughout Rhode Island—for

the locally administered general public assistance cases as well as the Federally aided categories of assistance administered by the State.

Payment within 30 days for services and supplies, they believe, has contributed to the success of the program.

provisions give added impetus to community health planning and health promotion and chronic disease control, he added.

Experience has indicated that no blueprint can be imposed upon any community, Cronin stated. Community rehabilitation projects, he said, might grow out of, or be centered in, a hospital rehabilitation program. They might be part of a broad chronic disease control plan. They might be sponsored by social agencies, workmen's compensation agencies, or a combination of agencies interested in problems of the disabled. Under the new amendments, two or more States may pool Federal grants for construction of a facility.

Rehabilitation Programs . . .

Amending legislation passed in 1954 has widened the scope of the Hill-Burton program to include nursing homes and rehabilitation facilities and has provided for the rapid expansion of the public vocational rehabilitation program.

Hill-Burton Amendments Include More Facilities

Nursing homes, chronic disease facilities, rehabilitation facilities, and diagnostic or diagnostic and treatment centers are now included in the Hospital Survey and Construction Program. Popularly called the Hill-Burton program, over the past 8 years it has approved projects providing more than 100,000 hospital beds and 483 health centers. The Public Health Service joins individual State agencies in administering the program.

According to John W. Cronin, M.D., chief of the Division of Hospital Facilities, Public Health Service, the expanded program offers a wide range of services for the chronically ill and the physically and mentally impaired. For rehabilitation facilities, emphasis will be on integrated medical, psychological, social, and vocational evaluation and services under competent professional supervision.

Legislation enacted in 1954 (Public Law 482, 83d Cong., 2d sess.) provides for fact-finding surveys to define needs of communities for rehabilitation facilities, as a prerequisite to developing State plans to meet these needs, Cronin said. Sur-

vey and planning grants are available to States on a dollar-for-dollar matching basis until expended.

In addition, grants to construct and equip rehabilitation facilities are authorized for the statutory life of the existing program—through fiscal 1957. The rehabilitation facility need not be part of a hospital, a revision contained in the new legislation. Funds allotted for rehabilitation purposes may not be transferred to funds allotted for other categories, but this provision does not apply to funds for chronic disease hospitals, nursing homes, and diagnostic or diagnostic and treatment centers. The new amendments also provide for maximum and minimum allotments.

Community Initiative

Essentially, the broadened program will operate like the original one, Cronin explained. Initiative for building facilities and their operation rests with each community. Each project is approved according to a State plan. Federal contributions range from 33½ to 66½ percent of the total project cost, as determined by the respective States.

Cronin noted that the act's integration features have important implications for interprofessional collaboration and performance. Its

Rehabilitation Program Hinges on Manpower

The success of the recently expanded Federal program for rehabilitation will depend upon the total available supply of qualified personnel, declared Catherine A. Worthingham, Ph.D., D.Sc., director of professional education, National Foundation for Infantile Paralysis, Inc., New York City.

Defining rehabilitation as total patient care rather than a specific group of techniques, Worthingham emphasized that a team of persons, including the patient, is needed if complete rehabilitation is to be achieved.

In addition to the physician and other professionally trained persons—nurse, physical therapist, occupational therapist, medical social worker, clinical psychologist, and vocational counselor—the family, the teacher, the religious leader, and the employer may be needed to complete the rehabilitation team, Worthingham stated.

The specialties and the type of rehabilitation facilities will vary in each case, depending on the patient and on the situation. Treatment

VOCATIONAL REHABILITATION

may be possible at home, or the services of a hospital or any of a large number of community services may be required.

In metropolitan areas and in medical teaching centers, rehabilitation centers, providing equipment and services at a centralized location, will be needed, Worthingham said, but in small communities, provision of complete facilities and personnel for small groups of patients is too

ber of students entering training and the capacity of schools to receive them, at the same time sparing no effort to protect the standards of education and practice, she said.

Personnel shortages in each field should be studied. Determination is also needed as to what these services are and what types of nonprofessional personnel can perform them. A balanced distribution of existing personnel in teaching, in

of the Office of Vocational Rehabilitation, outlined the main provisions of this new legislation which became Public Law 565 (83d Cong., 2d sess.) in August 1954.

As a result of its passage and supplemental appropriation legislation, States have increased latitude and increased Federal support with which to operate their rehabilitation programs, Gerber indicated. The new legislation provides for:

Research into the techniques and practice of social restoration of the disabled.

More facilities for the assembly of the necessary rehabilitation services.

Training of essential professional personnel.

Creation of a national advisory council on vocational rehabilitation.

The entire range of rehabilitation services provided under the program since 1943 is continued.

Since 1920

The public vocational rehabilitation program has been a Federal-State partnership from its inception in 1920, with the States operating their own service programs, Gerber said. In 1943, physical restoration services were added to the original program of job training, guidance, placement, and the purchase of prosthetic appliances, thus making it possible for the States to correct or minimize the disabling condition. With annual increases in appropri-

Existing personnel and increases needed for rehabilitation services in 5 fields

Type of personnel	Number available	Immediate increases needed	
		Number	Percent
Nurses-----	350,000	50,000	14
Physical therapists-----	6,000	2,500	41
Occupational therapists-----	4,000	2,900	72
Medical social workers-----	3,300	1,000	30
Vocational rehabilitation counselors---	1,200	500	41

expensive. Such areas must depend upon cooperation and communication between various types of rehabilitation facilities.

Use of Professional Personnel

According to Worthingham, immediate increases in personnel are needed in all fields essential to rehabilitation. The accompanying table shows these needs in five important fields.

Present estimates of personnel needs do not include statistics on employment or job vacancies except for hospital programs, Worthingham stated, and it cannot be determined how many employees are devoting their entire time to services for which they were trained. Nonprofessional personnel frequently can perform services for patients that will free professional personnel for the services that require professional training.

The maximum use of existing personnel is at best a stopgap, she believes. Concentrated effort must be made, therefore, to increase the num-

programs emphasizing prevention of disability, and in programs for care of the severely handicapped is also important, she said.

In closing, she stated that "orientation courses for existing personnel should result in better utilization of available manpower," and that "scholarships for students and financial assistance to professional schools is the only way to increase the manpower for rehabilitation services without sacrificing the quality of those services."

Vocational Rehabilitation Expanded by New Law

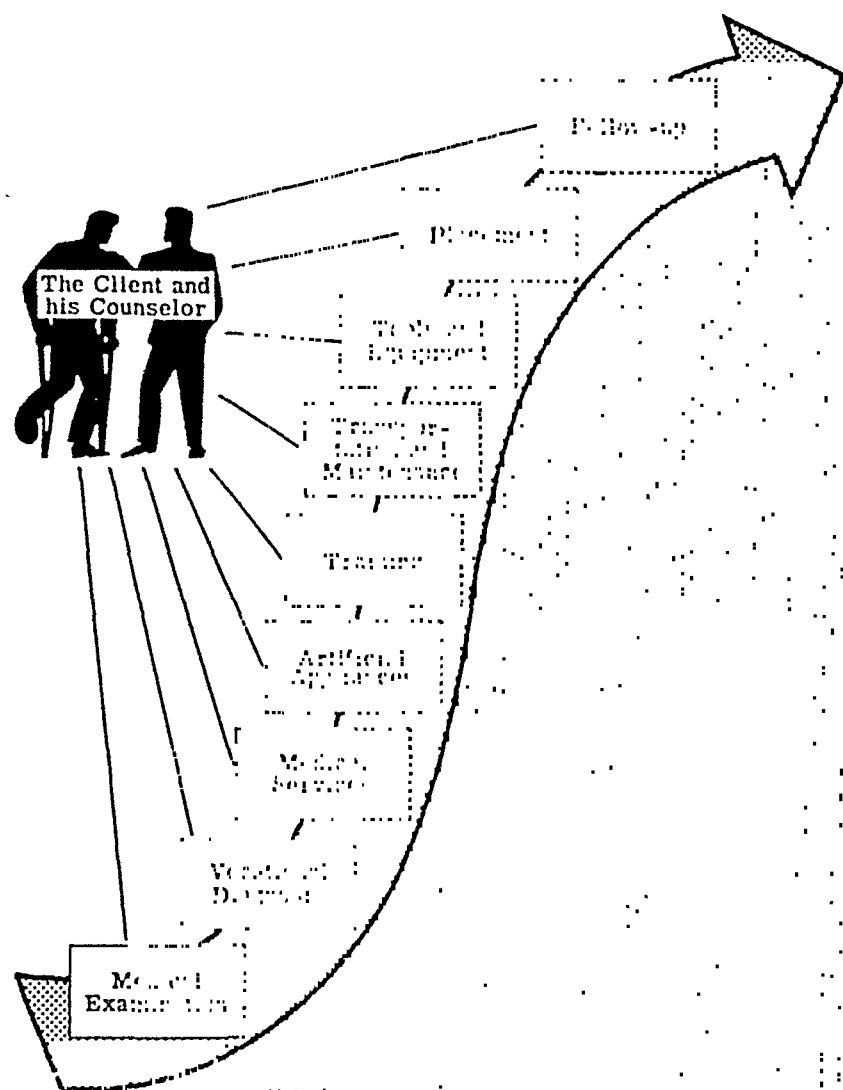

By the unanimous passage of amending legislation, the Congress has provided for the rapid expansion of the public vocational rehabilitation program.

Terming the program an investment in human welfare that is self-liquidating, Joseph Hanford Gerber, M.D., Dr.P.H., chief medical officer

Number of persons served and number rehabilitated, 1944-53

Fiscal year	Persons served	Persons rehabilitated
1944-----	145,059	43,997
1945-----	161,050	41,925
1946-----	169,796	36,106
1947-----	170,143	43,880
1948-----	191,063	53,131
1949-----	216,997	58,020
1950-----	225,724	59,597
1951-----	231,544	66,193
1952-----	228,481	63,632
1953-----	221,847	61,308

The rehabilitation process. Counseling and guidance is the core of all services.

tions, the number of disabled persons returned to gainful employment has rapidly increased.

No disabled person is considered to be rehabilitated until he has been placed in suitable employment, after being provided with substantial rehabilitation services, he continued. For services other than diagnosis, counseling, training, placement, and followup, the individual is expected to contribute to the cost according to his ability.

Gerber said the increased support to the States is provided by the new

legislation in three types of Federal grants-in-aid:

The basic support grant—allotted to the States on the basis of population weighted by per capita income.

The extension and improvement grant—allotted to the States on the basis of population. These funds are to be used for projects which will provide better vocational rehabilitation services. The Federal share may be 75 percent of the total cost of a project for a maximum period of 3 years.

The special project grant—made

to States and public and other non-profit agencies for the purpose of paying part of the cost of research projects, demonstrations, training and traineeships; and for projects to establish special facilities and services which hold promise of making a substantial contribution to the solution of vocational rehabilitation problems common to all or several States. In 1955 every \$2 of Federal money must be matched by \$1 furnished by the project sponsor.

Higher OASI Benefits Reduce Public Aid

The reduction in public assistance caseloads and costs resulting from the 1954 Social Security amendments were emphasized by I. Jay Brightman, M.D., M.S.P.H., in his discussion of the increase in Old-Age and Survivors Insurance benefits and the extension of the program to large new groups.

Dr. Brightman, assistant commissioner for welfare medical services, New York State Department of Health, noted that in February 1954 more than 460,000 aged persons were receiving both old-age assistance payments and OASI benefits. Many insurance beneficiaries, he pointed out, have required supplementary assistance if they receive minimum insurance benefits and have few other resources.

The increase in insurance payments has already permitted supplementary assistance to be discontinued for many beneficiaries, and a further decrease is expected, he said. Brightman also reported a decrease in caseloads and costs in the aid to dependent children category of public assistance.

Brightman believes that the higher degree of financial security offered by the insurance benefits based on the worker's own contributions, augmented by interest and dividends from previous savings and securities, and the current earnings allowed up

to \$1,200 a year, will have a significant effect on public health. Financial security should provide for a better emotional adjustment and decreased stress in the later years, and thus should become a potential force in reducing the prevalence of psychosomatic aspects of chronic illness, he explained.

For the less advanced forms of both mental and physical illness, financial security may permit an aged person to provide the necessary

services for himself and increase his chances of remaining in his own home or the home of friends and relatives rather than being institutionalized, he said.

The OASI amendment preserving the insurance rights of persons who become totally disabled before they have established permanent eligibility, Brightman believes, will stimulate interest in the rehabilitation of the disabled insurance beneficiaries whenever possible.

Housing code enforcement resulted in significant improvement of the housing quality by making the dwellings healthier and safer places to live. The improved maintenance should also prolong the usefulness of these houses.

The Study Procedures

The housing quality of the pilot study area was measured by the American Public Health Association's Appraisal Method for Measuring the Quality of Housing, which uses a penalty scoring method.

The "before" survey was made in May 1951, and the "after" survey in October 1952. In 1951 the survey area contained 1,042 dwelling units in 25 adjacent blocks, and the score was completed on 989 units. In 1952 the area contained 1,017 units and 976 were scored. About 90 percent of the units not scored were vacant, Johnson and his colleagues reported.

The 1952 survey was made after 18 months of enforcement effort. About 56 percent of the enforcement cases were already closed and most of the remainder were completed. Work in progress during the 1952 survey was given full credit in scoring, they said.

Results

The Baltimore Housing Code and related regulations did not, during the survey period, establish the same standards or even cover the same items used in the appraisal method, which, for the most part, is based on higher standards.

The study group reported the following results:

The average total dwelling score improved about 36 percent; facilities improved about 13 percent; maintenance, about 74 percent; and the occupancy improvement was not statistically significant.

The average gross rent increase amounted to \$5.70 from \$48.20 to \$53.90 per month. During the same time the median income of the families in the study area increased from \$239 to \$259 per month. Owner occupancy remained at 41 percent.

On Healthful Housing . . .

Housing code enforcement succeeded in remedying at reasonable cost substandard dwellings in a Baltimore area, a pilot study in housing rehabilitation finds. Prevention of blighted areas is also advocated in papers on planned inspections, communitywide planning of workers' new homes, and a PHS training course in housing hygiene.

Baltimore Housing Study Weighs Effects of Code

While modest rent increases may be expected from enforcement of a housing code in a housing rehabilitation program, the increases are not so large as to force low-income families to move, according to the results of the first detailed study of housing quality "before" and "after" rehabilitation.

The study, made in Baltimore, was reported by Ralph J. Johnson, M.S., chief, and Roy O. McCaldin, M.S., assistant chief, Housing Hygiene Activities, Division of Sanitary Engineering Services, Public Health Service, and Huntington Williams, M.D., D.P.H., commissioner of health, Baltimore City Health Department.

The scale of the study was not large, and the conclusions cannot be assumed to be representative of

housing rehabilitation in other cities or even in other parts of Baltimore, they warned, but if the basic information is carefully considered, it may provide an indication of what may be expected in other communities.

The Public Health Service provided general direction for the study, supervision of the field work, and prepared the analysis of the data; the Baltimore City Health Department provided the enumerators and related data and assistance, they reported.

Other conclusions cited from the study data were:

Compliance with minimum health and safety standards for substandard housing is possible without a directly proportionate rent increase since rent and housing quality were not found to have a reasonable relationship to each other either before or after rehabilitation.

education programs, sponsored by the National League for Nursing and the Public Health Service.

More Data Needed

To determine the cost of collegiate nursing education, the speakers said that more data are needed on:

The portion of general expenditures and the portion of expenditures for instructions that can be charged to nursing education.

The monetary value of all contributions from agencies participating in college nursing education.

The cost of the contribution of the school of nursing faculty to other hospital functions and to community service.

The cost of nursing education per student.

The part of this cost covered by tuition, student service, and other income.

When these questions are answered, the extent to which the data can help in estimating the cost of establishing new collegiate programs may be determined.

Few schools are able to answer these questions, the authors continued. "In view of the mounting concern over these special problems," they said, it was decided to study possible methods for determining the cost of basic collegiate nursing education in the university, including the hospital, the public health agency, and other participating groups.

In addition, they said, a manual is to be prepared describing a practical method of analysis by which the schools of nursing and their associated agencies could obtain first-hand knowledge of direct and indirect costs.

Twenty-eight general and special hospitals, 17 public health agencies, and 6 colleges and universities—the Loretto Heights College and the University of Colorado, Denver; Emory University, Atlanta; Skidmore College, Saratoga Springs, N. Y.; Syracuse University, Syracuse, N. Y.; and the University of Washington, Seattle—are partici-

pating in the project by testing tentative cost analysis methods developed for the study, Knott and Vreeland stated. They reported that the deans of these schools and their associates would hold a conference in December 1954 to discuss the soundness of the methods used in the schools, and that a manual based on their experiences is to be published in 1955 for use in a large number of colleges.

Because of their participation in collegiate training programs, public health nurses are deeply interested, particularly in the relation of this cost to public health nursing, Knott and Vreeland said. In conclusion, they stated that, although the answer to the question of determining the cost of collegiate nursing education is yet to be found, it is believed "that a reasonably sound method is emerging and the indications are that it will achieve its purpose."

Education on Medical Care Needs Investigating Spirit

For a disease as thoroughly worked over as tuberculosis, not even rudimentary knowledge exists of what might be called its "economy," despite the quantities of information available on costs.

In discussing professional education and medical care, the president of Johns Hopkins University, Lowell J. Reed, Ph.D., said the same gap applies still more strongly to knowledge of illness in general.

Professional schools—those of medicine, dentistry, and nursing—need to extend the student's knowledge concerning the subject of medical care so that he can approach the problem from the population point of view, with the involved interactions which this means, he observed.

"We need to know how a given illness, or illness in general, affects the society, and conversely the ways in which social organization and behavior affect illness," he said.

Reed used the phrase "medical

care" as meaning "an organized program having as its objective the prevention, diagnosis, and treatment of illness in the population, rather than in the individual."

He described the linking of medical care, in this context, with education as, first, acquainting professional students with organized health programs within health departments, labor unions, group clinics, and the like, and then preparing them for future participation, with their specific skills.

The professional school's concern, he said, should be with those factors and elements of medical care that have some bearing on all the professions, not on those specific to a particular profession.

What to Teach

That the need to know how illness in general, or a given illness, affects the society, and the reverse, was pointed up by the President's Commission on Health Needs of the Nation, according to Reed, also a member.

He commented that the fourth volume of the commission's report is the best existing compendium of information on this subject, but that it still lacks synthesis. Spotting these gaps in knowledge would be a challenging intellectual exercise, he observed.

What can universities teach when they are faced with a lack of an organized body of knowledge about medical care, Reed questioned.

Any of the subject matter now being presented in seminars, lectures, or field experiences pertinent to this field can be taught, he stated, pointing out that school administrators should be chary about teaching which might tend to solidify methods of medical service based on too little experimentation.

"All that I ask is that it be approached in the spirit of investigation on the part of both student and teacher," he said. The teacher, in presenting any specific idea, observation, or experience, should at-

tempt to answer the question as to where the experience fitted into the organized pattern of such knowledge, he suggested. Reed noted that almost without exception the highly successful programs touching on the field of medical care are associated with inspired teachers—those capable of lifting this material from its unorganized state and dramatizing it.

Urges Tests That Reflect Students' Real Progress

We must use tests which require our medical students to think and reason if that is our objective, said John T. Cowles, Ph.D., professor of psychology and assistant for personnel services, School of Health Professions, University of Pittsburgh.

Urging professors of preventive medicine to concentrate on the defining of educational objectives so that more adequate evaluative tests can be devised, he also said:

"To make real progress in medical education, whether through the day-to-day trial of a new teaching method by a single professor, or through much more elaborate experiments in curriculum revision involving inter-departmental coordination, we can never know that our steps are forward rather than backward except through carefully planned use of sound evaluative techniques."

Need Improved Techniques

In Cowles' opinion, the burden of evaluating a student's progress or final proficiency in the practice of preventive medicine falls upon the individual school, department, or professor, who can best solve the problem of adequate measurement by going beyond testing accumulated knowledge to using valid tests of complex skills and the nebulous factors that make up a personality.

Using clever questions, the newer objective tests now test the critical interpretation of experiments, the

solving of practical problems, the use of relevant versus irrelevant data, the adducing of hypotheses and their testing, and even the subtler points of diagnosis, treatment, and prognosis from unfamiliar case histories, he continued.

Cowles recommended that existing selection or achievement tests, such as the medical college admission test, the tests of the National Board of Medical Examiners, or other tests of reasonable promise, be given a thorough trial. Where written objective tests cannot serve, real effort should be expended to devise new kinds of evaluation measures, he said.

Teachers of medicine should participate closely in the construction of their own everyday evaluation instruments and make bold attempts to use the newer objective techniques, he believes. These, he said, should be as objective as possible, as statistically and educationally sound as can be assured by available criteria, and also practical and meaningful from the school's standpoint as well.

The great need for improved testing techniques, Cowles noted, was voiced by the 1952 Colorado Springs Conference on Preventive Medicine in Medical Schools and the 1953 teaching institute of the Association of American Medical Colleges.

Field Training Essential For Public Health Dentist

To provide public health dentists with a working knowledge and practical experience in dental public health administration, field training must become an integral part of graduate education, declared Philip E. Blackerby, Jr., D.D.S., M.S.P.H., director, division of dentistry, W. K. Kellogg Foundation, Battle Creek, Mich.

Opportunities for field training are not now available, he said, but organized attempts to make a systematic study of the problem and

to formulate plans for its solution are under way.

The fundamental objectives of field training are to provide students with a working knowledge and practical experience in general and dental public health administration, Blackerby stated.

An educational agency should have the primary responsibility for the planning and general supervision of a field training program, he said, and this institution should work closely with the service agency which functions as a training center. The responsibilities which each agency is to assume should be clearly defined, he said.

Training Facilities

Suitable facilities will be needed to carry out both the individual and the joint responsibilities of the school of public health and the field training center, Blackerby said. He suggested that the facilities of the field training programs operated by most of the States for other public health personnel be used for training public health dentists.

The centers selected should be desirably located geographically; supervised by a preceptor, preferably affiliated with the school of public health, who has the experience, interest, and capacity to train personnel; and have a suitable training program and a staff willing to evaluate and report on the progress of the trainees.

Problems to be solved will include financing the training center and at least partially subsidizing costs to the trainees, Blackerby stated. He suggested that State health departments be encouraged to develop field training centers for dental personnel and to give greater attention to dental public health in the field training experiences offered to other types of public health personnel.

He also suggested that schools of public health take a more active and direct interest in the organization and conduct of field training programs, both intra-academic and post-academic, for public health dentists

and for other categories of public health personnel, and that one or more pilot programs be established in selected States.

Dental School in London Rearranges Curriculum

Recent rearrangement of the 5-year course offered by the London Hospital Dental School represents a true experiment in undergraduate education, declared A. M. Horsnell, F.D.S., director of conservative dentistry at the school and dental subdean, London Hospital Medical College.

The children's dressership follows, for all practical purposes, immediately after the year of basic sciences, although it is actually preceded by an introductory course, in which periodontology, clinical examination routine with children as patients, instruction in local anesthetics, and a modified phantom-head course are given concurrently, Horsnell stated. Thus, students will continue directly from their study of physiology, anatomy, and embryology to the clinical observations of growth and development.

Under the plan, the students will be introduced in a logical way to dental pathology as it progresses in the month, he explained. Some 18 months to 2 years after they have completed their study of the basic sciences, when they know about preventive dentistry, periodontology, and restorative procedures, they will be taught dental prosthetics. They will then have a year or more in which to practice all aspects of dentistry concurrently. Dental mechanics, he said, will be taught as an adjunct to clinical prosthetics.

According to Horsnell's review of developments leading up to this arrangement, one important feature is the placement of the children's dressership early in the curriculum. Study of the traditional program, in which this dressership came late, indicated that the students were merely fulfilling the minimum re-

quirements and that only in isolated instances did they or their young patients gain any real benefit from the dressership. "We began to wonder whether this placement of the dressership was giving the impression that there must be something difficult about the treatment of children," he said.

Horsnell reported that some 2 or 3 years ago pedodontics was made the first dressership, with the following results: These trainees have shown by far the greatest aptitude for children's dentistry; the patients have received their dressers with greater enthusiasm; more complete treatments and followups have been accomplished; and, incidentally, these trainees have turned out a much higher quality of general restorative dentistry.

Postgraduate Education

Another postwar development of particular significance is the increase in postgraduate study, Horsnell maintained. In this connection he mentioned the establishment of the Institute of Dental Surgery, which is closely associated with the London University, the Royal College of Surgeons, and the Postgraduate Medical Federation, and he noted that the Royal Colleges have established their own dental faculties and examinations for the fellowship in dental surgery.

The National Health Act of 1948, he reported, made provision for persons engaged in its service to attend postgraduate refresher courses, such courses to be given by the universities in conjunction with the Ministry of Health. These courses have the support of the British Dental Association and are getting under way, he said.

Awareness of Dental Health

As a factor related to dental education in Great Britain, Horsnell emphasized the increased awareness of dental health on the part of the population, with a concomitant increase in the demand for treatment.

"Under these circumstances, the number of applicants now seeking entry into our schools cannot be considered satisfactory," he stated.

Horsnell also emphasized the intimate relation between recruitment and dental education in its broadest sense. "A fuller appreciation by the public of the benefits of dental health and the cost of dental disease automatically produce a greater demand for trained personnel," he said. "Greater dental consciousness would raise the status of the profession, and if the status is raised, there is little doubt that the number of recruits would similarly be raised."

He pointed to "good treatment to the proper section of the population" as the surest way to educate the public in dental matters, and he indicated that children represent the proper section of the population.

Stresses Field Experience For Training Teachers

How professional laboratory experiences are being used to equip prospective teachers in health education was the topic of a report from Edward B. Johns, Ed.D., associate professor of health education, University of California, Los Angeles.

The concept of laboratory experiences in education, Johns explained, is best clarified in the definition prepared by the American Association of Teachers Colleges:

"Professional laboratory experiences include all those contacts with children, youth, and adults (through observation, participation, and teaching) which make a direct contribution to an understanding of individuals and their guidance in the teaching-learning process."

Johns noted that one result of these experiences is greater participation in community activities on the part of teachers. He remarked that between 40 and 45 teacher education institutions today offer cur-

riculums to prepare school health education personnel, a significant trend which is highly endorsed.

From a 1953 survey of 34 institutions having such curriculums, Johns selected these indicators of the need for more purposeful laboratory experiences (they are based on data classified under three categories—laboratory experiences prior to student-teaching, experiences during student-teaching, and community field experiences):

The lack of understanding of the school health program on the part of administrators is a major problem.

The procedures utilized before and during student-teaching are in accordance with accepted educational standards.

More than half of the institutions surveyed have a course on field experiences in health education or they include, in other courses, actual work experience in the community. The other institutions are depending on observation of community health agencies as their chief type of field experience.

There is need for the inclusion of additional laboratory experiences and for improvement in the quality of present experiences in the three categories, but particularly in the area of community field experiences.

A large majority of the institutions stated that they plan to increase their offerings in field experiences in the near future.

Washington Health Officers Find Institute Stimulating

Institutes are an effective method of imparting to public health officers knowledge concerning interpersonal relationships and the influence of emotional factors in disease processes, according to Herbert S. Ripley, M.D., and Leland E. Powers, M.D., M.P.H. In addition, staff relationships may be improved by the change in views and attitudes, they said.

Dr. Ripley is professor and executive officer, department of psychiatry, University of Washington School of Medicine, Seattle, and Dr. Powers, formerly professor and executive officer in the university's department of health and preventive medicine, is with the department of preventive medicine and public health, American University of Beirut, Beirut, Lebanon.

Interest in mental health as a part of public health and preventive medicine has increased during the last few years, they said, and teaching institutes have been held from time to time since 1948.

Organization

The mental health institute held at the University of Washington in Seattle in 1950 was attended by 39 public health officers, they reported. The students were organized into small discussion groups, each led by a public health administrator and a psychiatrist.

Orientation discussions by the teaching staff were followed by attendance at medical wards of the county hospital, wards at the tuberculosis sanatorium, clinics, and informal seminars. In the evening there were informal discussions and debate on subjects such as the relationship of the health department to the general public and to the schools, the churches, private and governmental agencies, and physicians.

Replies to questionnaires sent to all participants a year after the institute was held indicated that the students were satisfied with the general methods used in conducting the institute and that the attitudes and knowledge gained had been widely applied in their daily work, the speakers reported.

Informal personal visits to 13 health departments suggested that "changes that cannot be accurately measured had occurred with a trend toward more skill and understanding in dealing with individuals and groups, better staff morale in the health department, improved atmos-

phere in clinics, closer relationship with the community as a whole, and better appreciation and utilization of available facilities."

The questionnaire revealed that the participants overwhelmingly favored the centering of institute discussions around patients, allocating more time for informal discussion than to clinics, and a maximum 1 hour a day formal lecture session. The participants also felt that 7 to 10 days should be set aside for an institute, and that the participants should decide how much time should be spent in clinics and for discussion of a particular problem.

Ripley and Powers said that the State and Provincial health directors who had observed the participants for 2 years reported that at least two-thirds of them had benefited from the experience. They also reported that at a 3-day refresher meeting held in 1953, two-thirds of those attending had been students at the original institute in 1950. The participants in the refresher institute showed a vital and active interest throughout the meeting, and there was a unanimous expression that the institute had been stimulating, interesting, and helpful in carrying forward professional responsibilities.

Cincinnati Health Teachers Get Inservice Education

Health teachers participate in all phases of Cincinnati's inservice teacher education program, which ranges from extracurricular committee work to professional and cultural study with academic credits, said William K. Streit, Ed.D., director of health and hygiene in the city's public school system.

Cincinnati's program is unusual in that there is no released time for committee work, Streit said. The program places major emphasis on committee work to which members of the school staff contribute their

ideas. These activities include curriculum revision, teacher self-appraisal, appraisal of textbooks, teaching materials, and visual aids as well as many opportunities for child study and self-development through workshops, institutes, preparation of publications and scripts, and specially planned meetings.

Teacher committees have helped develop Cincinnati's health courses at various school levels, he said. In this, they have outside cooperation from the health department, the Academy of Medicine, the Public Health Federation, representative parents, and various health and welfare organizations.

Textbook committees, working at four grade levels in health, evaluate textbooks for curricular criteria, authorship, organization of content, motivation, style, vocabulary, illustrations, and format, he said. Publishers, as well as the city's board of education, are guided by these recommendations, he said.

Three subcommittees appraise supplementary teaching materials in the field of health, Streit said. As a combined committee, in 1953-54 they previewed 421 health and safety films and graded and grouped the films according to units of study. This group also works with the Visual Aids Exchange and the Museum of Natural History in Cincinnati in appraising models and charts for health teaching.

Health teachers took a 40-hour course in driver education in 1953-54 because this phase of safety has been incorporated into the 10th grade health program, he said. Also, at the annual 4-day teachers institute, 4 sections of interest to health and safety teachers were scheduled.

Mental Health Stressed In Teacher Training

The emphasis in on-the-job training programs has shifted in recent years from subject matter and teach-

ing techniques to the teacher's relations with pupils, parents, and the community, according to Jennelle Moorhead, M.S., associate professor in the general extension division of the Oregon State system of higher education.

In that shift, the mental health aspect of those relationships is of increasing concern to school authorities, she said in summarizing the report of the American School Health Association's Committee on Mental Health in the Classroom.

The report discussed some of the principles to be followed in setting up mental health training programs, indicated frequently encountered problems, and reviewed a number of programs employing different and difficult approaches. The report pointed out the following:

The purpose of inservice training in mental health is to help the teacher attain greater self-knowledge and more insight into the meaning of children's behavior. The beginning teacher may be bewildered to find that, despite excellent preservice training, he was prepared for ideal situations rather than overcrowded classrooms. It is precisely in the area of establishing satisfactory home, school, and public relations that preservice training is weakest. These combined problems may affect the beginning teacher's mental health.

The experienced teacher may be unaware of how much has recently been learned in the field of child behavior, growth, and development, and there is much he could learn in an inservice training program.

Teacher Objections

However, teacher opposition may be encountered in setting up inservice training programs in mental health. Many teachers resent giving up their time. Others regard the programs as an implied criticism of professional ability. Some may resent any disturbance of their teaching patterns, while others have never worked successfully in groups and fear any group experience. All these

attitudes are mental health problems. These teachers need help in improving their own human relationships before they can understand and help the children in their classrooms.

The objectives of training programs in mental health can best be achieved by arousing the teachers' enthusiasm which depends largely on the part the teacher has in planning the programs. The training should grow out of the felt needs of teachers, and the entire school staff should participate. Parent participation, to bridge the gap between home and school, is encouraged.

Superior Program

Enrollment figures for education classes in mental health at the University of Michigan and Wayne University indicate the success of the Detroit school system in arousing teacher interest.

When the Detroit program was started in 1947, the two universities jointly offered a 16-week course which included half hour showings of films and transcripts, an hour's lecture by a psychiatrist, professional educator, or social worker, and an hour of discussion. By July 1952, the course had been given 15 times with an enrollment of 2,856. Advanced courses attracted an enrollment of 558. A total of 3,680 school staff members attended short courses of three meetings each.

The Detroit program featured the visits of a psychiatrist to classrooms one afternoon each week to discuss his observations with the teachers. Similar programs are being carried out in Los Angeles and Madison County, Ill., and by State education departments in Massachusetts, Oregon, and Pennsylvania.

School systems throughout the country are coming to realize that teachers should have the same skill in recognizing mental illness among children as they now show in detecting physical handicaps.

Epidemiological Studies . . .

What clues have been uncovered as to the causes of the recent outbreaks of infantile diarrhea? Investigators report their findings as well as observations on shigellosis, infectious hepatitis, and toxoplasmosis. In another report, healthy bats are suspected as rabies carriers.

Links Ohio Outbreak To Environment

A contaminated environment may have a major part in the spread of infantile diarrhea in a hospital nursery.

This was the conclusion reached during a 2-month outbreak of contagious diarrhea among young babies in Children's Hospital, Columbus, Ohio, late in 1953. As a result of this experience, measures to prevent the spread of this infection in the hospital have been modified and improved.

So stated Warren E. Wheeler, M.D., professor of pediatrics, Ohio State University, Frederick Wentworth, M.D., communicable disease division, Ohio Department of Health, Bertha Wainerman, M.D., and R. T. Ravenholt, M.D., of Columbus.

They reported that the source of the outbreak could not be determined, but that the increase in infantile diarrhea cases admitted to the hospital in the fall of 1953 apparently reflected the prevalence of infections with *Escherichia coli* O111 in the community.

Twenty-seven infants in two nurseries and nine adult contacts among the hospital personnel were involved in the outbreak. Five of the babies acquired their infection at home. Three of the hospital personnel were porters who cleaned the rooms but had no direct physical contact with the babies.

One nursery contained a diarrhea unit and a respiratory unit. The same treatment and utility rooms

were used for both units, and the same resident physicians and nurses cared for the patients. The other nursery was used chiefly for surgical cases and had its own physicians and staff nurses, who cared only for the patients in this nursery. The nursing supervisor and some of the housekeeping personnel, however, served both nurseries.

Treatment and Prophylaxis

Specific treatment with chloramphenicol, neomycin, or oxytetracycline was given, along with symptomatic treatment and water and electrolytic replacement therapy. Penicillin, sulfadiazine, or both, were given to most babies in an effort to prevent respiratory infections.

Prophylactic administration of chloramphenicol failed to prevent cross-infection—half of the babies developed resistance to the drug—but positive cultures declined sharply after beginning neomycin therapy. All babies who received chloramphenicol or neomycin also were given vitamin K.

Evaluation of environmental contamination was attempted during the latter part of the outbreak. However, at that time, the outbreak was almost under control, and, perhaps because of therapy, only a few organisms were found.

Wheeler and his co-workers pointed out that a nursery in a general children's hospital cannot be closed when a diarrhea epidemic occurs. If the disease is present in the community, the hospital must be prepared to receive infants who have the disease.

They recommended that at the beginning of an epidemic in a hospital ward, no babies under 6 months old be admitted until it is reasonably certain that the epidemic is under control. Babies under 2 months old are very susceptible to infection with *E. coli* O111, and the cross-infection rate is much higher in this age group than among older infants.

Wheeler and his colleagues also recommended that chloramphenicol not be used as a preventive agent because of the resistance to this drug developed by this strain of *E. coli*.

One of the measures taken by the hospital was to see that personnel acquiring the infection were treated with neomycin and excluded from work until a negative culture was obtained.

Shigellosis Agent Shift Found in Two Epidemics

A dysentery epidemic may be viewed as a dynamic process in which different serologic types exhibit varying degrees of success in invading the host population. Lt. Col. Robert B. Lindberg, MSC, USA, and Kenzo Okabe, Ph.D., concluded after observing shigellosis outbreaks among prisoners of war in Korea and Japanese civilians in Tokyo from 1950 to 1953.

Colonel Lindberg is in the Department of Bacteriology, Army Medical Service Graduate School, Walter Reed Army Medical Center. Dr. Okabe is in the Department of Chemistry, Japan Armed Forces Medical Laboratory, Kurihama, Japan.

Shigellosis, they said, is a disease of classic importance in military medicine and among civilians displaced by war or natural disaster. But recently developed techniques for distinguishing *Shigella* strains by antigenic analysis, they continued, have not been widely used to study causative types in epidemics.

In both the Tokyo and Korean outbreaks of bacillary dysentery, the

predominant etiological agent, according to Lindberg and Okabe, was a *Shigella flexneri* type or group of types which was replaced by another *flexneri* strain during the 3-year period.

The situation in metropolitan Tokyo, where reported cases of bacillary dysentery rose from about 58,000 to over 100,000 per year between 1951 and 1953, was the simpler of the two, they said. One preponderant type, *Shigella flexneri* 2a, was slowly but consistently replaced by the closely related but biologically distinct type 2b. *Shigella sonnei* and several less frequently occurring *flexneri* types were constantly present but did not fluctuate markedly in incidence.

Situation Contrast

The epidemic in Korean prisoner of war camps was much more severe than the outbreak in metropolitan Tokyo, Lindberg and Okabe reported, and since the camps had a confined, although shifting, population living under less than optimal conditions of sanitation, the circumstances were quite different. The carrier and contact rates, they continued, were undoubtedly greater in Korea. However, they found a comparable fluctuation pattern in type incidence.

Two types, *Shigella flexneri* 4 and 3, dominated the Korean epidemic at its start. But they diminished in consequence while types 2a and 5 rose steadily to comprise the major causative agents at the end of the outbreak.

Speculations

There is no established reason, said Lindberg and Okabe, for the type shifts reported in these epidemics. Since it has been suggested that people might develop immunity through contact with the original causative agents, Lindberg and Okabe agreed that this factor might be significant for epidemics among a closed population. But they doubted that an immune group could be altered as rapidly as ob-

served outbreak conditions in Japan would demand.

Another speculation, they said, concerns the role of bacteriophage in the destruction of predominant types. In this connection, it has been surmised that the alterations might represent abrupt genetic changes among the *Shigella* organisms. Lindberg and Okabe said they found no grounds for assuming the operation of such a mechanism in these epidemics.

They pointed out the necessity for continued observation of dysentery epidemics if the significant types are to be recognized. This recognition, they continued, is the essential basis for control of carriers.

Reviews Toxoplasmosis, Urges More Study

The incidence of toxoplasmosis in different locales varies sufficiently to require examination of multiple serum samples from a patient suspected of having acquired the disease, noted Harry A. Feldman, M.D., in discussing various laboratory and epidemiological aspects.

Dr. Feldman is associate professor of medicine, State University of New York, Upstate Medical Center, Syracuse.

Many times a clinical syndrome has been related to infection by *Toxoplasma gondii* because antibody is detected in a single serum sample, he stated.

From studies of the "normal" populations of some 11 different areas of the world, he presented several examples to show why a single sample may not be sufficient.

A positive test may have considerably more significance in some areas than in others, he said.

Feldman used lantern slides to present his evidence on how and where man acquires this infection and made the following observations:

1 From information gathered from congenital cases, different seasons apparently do not carry significantly

different degrees of risk for acquiring infection.

2. From tests of various animal serums for antibody content, dogs and cats appear to be possible reservoirs for the disease in humans.

3. There is no evidence as yet that the disease is transmitted from human to human. It has been found, however, that most husbands of mothers of congenitally infected infants have no serologic evidence of previous infection.

More studies of "normal" human and animal populations are needed to complete the information on the spread and acquisition of the disease, he pointed out.

Diagnostic Procedures

Feldman discussed four procedures for diagnosing toxoplasmosis: isolation of the organism from tissues and cerebrospinal fluid, the dye test for serum antibodies, the complement fixation test, and the skin test.

Noting that the dye test is an extremely sensitive method of demonstrating antibodies for *Toxoplasma*, he outlined the procedure.

Dye test antibodies develop quickly, reaching high levels within about 2 weeks after onset of infection, and persist in a slowly diminishing titer for many years if not for the life of the individual, he remarked.

Since complement-fixing antibodies appear slowly and tend to disappear fairly rapidly, it is possible to encounter a highly positive dye test in the presence of a negative complement fixation test, he pointed out, recommending that if there is any question about the serologic data, a second serum be examined about 2 weeks after the first.

If the complement fixation test remains negative, the probability that there is an active infection can be discounted, he said.

In Feldman's opinion, the skin test is of no value in a specific diagnostic problem. If it has any usefulness at all, he said, it is as an epidemiological tool in surveys.

The newer serologic procedures,

he commented, have helped elucidate the spectrum of the clinical expression of infection with *Toxoplasma*. For example, it is known that congenital toxoplasmosis may be manifested by chorioretinitis, cerebral calcifications, disturbances in the head size, psychomotor retardation, and convulsions, he stated.

He said he found almost every surviving patient to have had chorioretinitis and about half to have had each of the various other evidences of damage.

Seek Clues to Outbreak Of Infectious Hepatitis

An outbreak of infectious hepatitis in a suburb of Detroit, Mich., during the fall and winter of 1953-54 emphasizes the difficulties surrounding the epidemiology of this disease, maintained William R. Stinger, M.D., M.P.H., of the Wayne County Department of Health, Eloise, Mich.

These difficulties, Stinger said, are: (1) the existence of subclinical infections, (2) nonspecific laboratory tests, (3) varying clinical manifestations, (4) poor reporting, and (5) multiple transmission routes.

The outbreak also emphasized that good personal hygiene and the proper disposal of sewage are of utmost importance in the control of infectious hepatitis; that children are attacked more frequently than adults; and that gamma globulin is an effective prophylactic agent when administered prior to the prodromal stage of the disease, Stinger declared.

Positive diagnosis of infectious hepatitis was established for 42 persons, not including any person without clinical or laboratory evidence of liver involvement. The outbreak attracted attention in January 1954 when a public school principal reported that several students and a teacher were absent from school because of jaundice, Stinger stated.

Investigation by the health department included, first, interviews

with school authorities, patients, parents of patients, and attending physicians, and, second, interviews with all students and teachers who had been absent from school during October, November, or December and consultations with local physicians and clinic and hospital personnel, he said.

Of the 36 school children ill with infectious hepatitis, 32 attended the school from which the report came, Stinger said. Another patient was a teacher at this school, and 4 more patients were household contacts of one or more of the children at this school.

Survey of Sanitary Facilities

Stinger reported that a survey of the sanitary facilities at the school where the initial cases occurred revealed several situations that suggested the possibility of back-siphonage of sewage into the school's water supply.

It cannot be proved, however, that any of the conditions were partially responsible for transmission of the disease in this outbreak, he stated.

The survey also indicated that, although facilities for hand-washing were available, soap and towels were often lacking, he added.

Concerning sex and age distributions of the cases, Stinger reported that 26 of the patients were males and 16 were females and that 35 were in the age group 5 through 14 years.

He pointed out, however, that the age distribution may be partially due to more intense case finding in the school populations.

Interviews of household contacts of all patients about 3 months after the onset of the last reported case showed that only 1 case of infectious hepatitis occurred among the 67 contacts who received gamma globulin. This person, however, had received the globulin 4 days prior to the onset of the disease, Stinger noted. Four cases occurred among the 64 contacts who did not receive the globulin, he specified.

Healthy Bats Suspected As Rabies Carriers

The Mexican free-tailed bat may be a carrier of the rabies virus, preliminary studies in Texas have revealed. This insectivorous species, *Tadarida mexicana*, is a member of the family Molossidae, whose habitat in this country is Texas and other westward States.

As a result of their studies, Lt. Col. Kenneth F. Burns, VC, USA, and Col. Charles J. Farinacci, MC, USA, of the Fourth Army Area Medical Laboratory, Fort Sam Houston, reported finding the in-apparent infection of this species with the virus of rabies. This new observation, they said, has considerable epizootiological and epidemiological significance, suggesting the existence of "healthy carriers of this disease." Seven cases of human rabies were reported in Texas during 1952-53.

The feeding and breeding habits of *T. mexicana* permit chance rabies infection from the bites of a known carrier, the vampire bat *Desmodus*, they noted. Recent reports of bats attacking humans and the confirmation of rabies in insectivorous bats offer an additional explanation of how the disease may move from place to place in rapid succession, they explained. Attacks on one species by another have been witnessed. Infected vampire bats may therefore transmit rabies to insectivorous bats under natural conditions. Insectivorous bats, when rabid, may bite other mammals.

Burns and Farinacci speculated about the possibility that *T. mexicana*, even though apparently normal and healthy, may constitute a reservoir of rabies. This would lead to the perpetuation of the disease in wildlife and to the occasional infection of humans, they said. The higher the incidence of rabies in animals, the greater is the opportunity for human rabies, the officers said. They urged control measures aimed

at reducing possible reservoirs of rabies.

The Bat Survey

According to the researchers, a bat survey was begun early in 1954 at the Brooke Army Medical Center, Fort Sam Houston. Only the external characters of the bats collected were identified; all were classified as *T. mexicana*.

The first collection netted 32 apparently physically normal bats. At the time of the second collection, which yielded 35 bats, deranged behavior, muscular tremors, urine incontinence, and parietic manifestations were observed among the bat population. Scores of deaths were recorded. At first these symptoms were attributed to the effects of an intensified DDT program in the area.

While the DDT program was under way, five additional bats were brought in. One was found in a state of spastic paralysis, hanging from a screen door. Three others evidenced paralysis, and the fifth had symptoms of encephalitis. Other collections of apparently normal bats were later taken.

All collections produced 207 bat serums which were divided into pools and stored at a freezing temperature until tests could be performed. Neutralizing antibodies were observed in the serums from apparently normal healthy bats, indicating past experience with rabies. Statistical significance was attached by Burns and Farinacci to the high percentage of bat serums which were positive for neutralizing antibodies. Inactivation of the bat serums did not eliminate the rabies virus neutralizing substance in the blood.

Burns and Farinacci said, "The plausible explanation appears to be that this virus inactivator is specifically related to immunity."

Two isolates were obtained. Tests with infected mouse brain tissue against known rabies immune horse serum demonstrated that the immune serum neutralized both its homologous virus and the two newly isolated bat strains. Negri bodies had

previously been observed in the brains of the bats from which the isolations were made.

"The high percentage of bat serums which contain neutralizing antibodies is probably a result of sur-

vival from rabies infection, possibly in inapparent form," Burns and Farinacci suggested. However, the presence of rabies virus in the brains of nonsanguivorous bats does not necessarily establish that they are

William Thurber Fales

Dr. William Thurber Fales' concept of the service a vital statistician can give to the community in which he lives and works may prove to be his greatest contribution to his chosen field of demography.

Dr. Fales, whose home base from 1934-53 was the statistics section of the Baltimore Health Department, saw very clearly the value of the registrar function to the individual citizen, the clinician, the epidemiologist, and the health administrator.

But he also had the idea that vital statistics were "vital" and were related to such varied social programs as education, traffic provisions, housing, policing, and recreation.

It was this concept that led him to obtain population tabulations for the city of Baltimore on the basis of enumeration districts and to work with the Bureau of the Census in 1940 in developing enumeration districts that could most easily be correlated with the subareas a city uses for administrative purposes—school, police, voting, and health districts.

It took Fales some time to get this material into shape and to correlate it in a working fashion with the flow of births and deaths—his primary task. When he once had this information, he was the demographer for the city by the sheer force of the fact that he knew more about the population of Baltimore than anyone else—and he gave what he knew in order that the data might obtain their greatest usefulness.

Many times, reports and activities completely changed form and direction after city officials had consulted Fales.

Fales engaged in national and international activities—such as the National Health Inventory, the President's Commission on the Health Needs of the Nation, and the International List of Diseases and Causes of Death—as well as city and State. But he always kept clearly in mind the fact that the force of his contributions to social problems came from his knowledge of vital statistics and from his ability to apply this knowledge to the problems at hand.

I feel sure that any trained vital statistician who can get Fales' concept of the power that comes from knowing more about the population and its flow of births, deaths, and migration than anyone else in the area can carve out for himself a career as interesting and valuable as Fales'.

—LOWELL J. REED, *President,*
Johns Hopkins University

capable of transmitting the disease, even though unprovoked attacks on humans by certain of these species are known to occur, they remarked.

Oral Penicillin Effective In Navy Outbreaks

Oral penicillin offers a safe, practical, and inexpensive way to control epidemics of streptococcal infections, according to Comdr. John R. Seal, M.D., head, Communicable Disease Branch, Preventive Medicine Division, Navy Department.

Penicillin prophylaxis is not considered a desirable or final answer to the problem of controlling epidemic streptococcal infection, he declared. Rather, it is an interim measure to allow emergency control, he said.

Epidemics of streptococcal infections and rheumatic fever can be abruptly terminated through the use of 500,000 units of oral penicillin daily, he said.

If continued for 10 days or longer, this dosage will eliminate streptococci from most infected persons and provide more or less prolonged residual suppression of an epidemic, he said.

Reactions to oral penicillin are negligible, and strains of streptococci resistant to this antibiotic have not been found, he asserted.

Objectives and Results

Studies were started in 1951 to find the smallest dose of oral penicillin which would effectively suppress streptococcal epidemics and to learn the smallest practical dose for prophylaxis, Seal related.

Doses from 50,000 to 500,000 units daily were used for suppression of epidemics, he said. All doses employed seemed to have some efficacy in converting throat cultures from positive to negative, he remarked, but it was not until a dose of 375,000 units daily was reached, that a marked decline in carriers resulted.

The most dramatic effect was obtained from a dosage of 500,000 units of penicillin daily, he said.

Treatment was begun on a Saturday night. On Sunday, 2 patients with scarlet fever and 1 with clinical evidence of other streptococcal infection were found. Thereafter, during 2 weeks of prophylaxis, he reported, no further patients with streptococcal infection were found.

No rheumatic fever occurred in one regiment in an 18-week period following the end of a course of prophylaxis with 500,000 units of oral penicillin after 12 cases had been admitted in the 7 prior weeks, he reported.

Results with a single daily dose of 50,000 units in two other regiments differed considerably from those obtained with 500,000 units, he commented.

Admissions for streptococcal infections were markedly reduced, but not terminated, and the relative prevalence of specific types of streptococci was not altered, he said.

Carrier rates and the frequency of rheumatic fever seemed to be reduced, he added.

Reactions, Costs

With few exceptions reactions to oral penicillin were a mild, transient urticaria, he said.

Of 39,615 recruits treated with penicillin, 134, or 0.34 percent, reacted, he reported.

The average cost of 250,000 units of oral penicillin twice daily is about 3.3 cents per day per man in military populations, he reported.

The 50,000 unit dose costs less than one-half cent per man per day, he added.

Care of the Chronically Ill . . .

Progress in the control of chronic disease is reported and suggestions are made for greater progress in the future. Referral systems, rehabilitation of "poorhouse" inmates, conservation of hospital services, epidemiological and statistical studies, and new laboratory tests to diagnose the chronic diseases will help to develop procedures for the care of the chronically ill and for the restoration of many of them to useful life in the community.

Facilities Planning Accents Chronic Disease Problems

The new medical facilities survey and construction program offers States and communities the opportunity of crystallizing their thinking on the whole chronic disease problem, according to Surgeon General Leonard A. Scheele.

Under the new act, fiscal year 1955 appropriations amount to \$2 million for use of States in conducting sur-

veys to determine their needs for chronic disease facilities, diagnostic treatment centers, nursing homes, and rehabilitation facilities. A \$21 million construction appropriation has been made available until the end of fiscal year 1956.

Although the current level of appropriations will not add more than a drop to the almost empty bucket of facilities, the Surgeon General said, the initial projects can be courageous experiments—beacons in each State and throughout the country.

Or they can be "just more space-fillers," capable only of perpetuating many past errors in dealing with long-term illness.

The Surgeon General stressed the need for finding better ways of financing long-term care and for the adoption of new concepts about chronic illness.

Financing Rugged

Voluntary health insurance has made an excellent start, but current insurance benefits tend to pick up only the small end of the check, he said, adding that the resources of the patients and their families, as well as of public and private welfare agencies, public medical and hospital programs, and philanthropic institutions are severely taxed to carry the residual burden of long-term illness.

He expressed the hope that voluntary health insurance agencies, along with other private and public organizations, will develop and test in communities new plans for a more equitable distribution of the medical and hospital expenditures for long-term illness.

New Concepts

Concepts generally held for the past half-century tend to equate long-term illness with incurable diseases that follow a rigid pattern of degeneration and death or with invalidism as an inevitable event in old age, he said. Regrettably, he added, these concepts also foster the assumption by society that the only solution is to provide enough institutions in which to store the unwanted victims of long-term illness.

We are learning, he said, that prolonged disability can be transformed into prolonged ability to work and live like healthy folk, or at least to take care of one's daily needs with little or no help.

The Surgeon General called for the acceptance of the concept that most of the patient's care can be provided in facilities within his own community. "Until we get that new concept firmly fixed in our think-

ing," he said, "we will go on emphasizing first the large and costly outside institution, and only last—perhaps too late—will we turn to the community general hospital and its outpatient department, the community health department, the local physician's office, and the patient's own home as appropriate settings for his continuing care."

Citing the community need for more different kinds of services than are commonly available today, he pointed out that only a few large cities have developed to a reasonably high degree home care programs which include medical, nursing, social, and housekeeper services, and physical therapy; ambulatory services offering diagnosis, therapy, and followup; and comprehensive rehabilitation services.

He discussed, as other important parts of the chronic disease picture, research and experimentation in care, combined planning by all the groups involved, and scrutiny by each organization of its own policies and operations in the whole area of long-term illness.

Study and Research

The Surgeon General gave as an example of the studies and demonstrations needed in the whole field of long-term illness the projects of pioneering mental institutions. Some mental institutions, he said, "have made additions to their professional staffs for intensive treatment of selected patients who have been returned to their communities under hospital supervision. Others have set up outpatient departments, thus shortening the stay of many patients and avoiding many readmissions. Some are experimenting with foster home care; others with arrangements for allowing rehabilitated, but homeless, mental defectives to work in the community and return to the institutions at night."

In line with integrated effort, the Surgeon General reported that an Inter-Bureau Committee on Chronic Illness has been set up within the

Public Health Service's Bureau of State Services and includes representation from the Office of the Surgeon General, the Bureau of Medical Services, and the National Institutes of Health. The committee has a charter, he said, to explore and report on all Public Health Service activities in the chronic illness field—research, medical and hospital services, facilities, and public health programs.

Maryland Referral System Set Up for Chronically Ill

A referral system that will help each chronically ill patient find and use the most appropriate community service and thus use the chronic disease hospital only when he belongs there was advocated by V. L. Ellicott, M.D., Dr.P.H., acting director, chronic illness program, Maryland State Department of Health.

Many chronic disease hospital beds are filled by custodial patients whose conditions cannot be improved. Such usage interferes with the hospital's primary function as a dynamic treatment center, Ellicott declared.

In the absence of adequate referrals, he said, the new patient who should go to a nursing home is too frequently allowed to go to the chronic disease hospital simply because the path to the hospital is established while the path to the nursing home is not. The patient who is due for a transfer from the hospital to a nursing home will stay in the hospital if no one is made responsible for finding a bed in a nursing home or because a technicality prevents a welfare board from certifying his financial status, he added.

Integration of the services of the chronic disease hospitals, the other hospitals, nursing homes, welfare boards, local health units—which provide health services to patients at home—and various other participants, Ellicott said, requires agree-

ment on the following basic concepts:

1. The patient must be able to reach any service he needs, whether it be rehabilitation or custodial care, and whether the patient is indigent or not.

2. Provision must be made for social service guidance and for smooth and prompt transfer of the patient from one service to another.

3. A competent agency or group must assume responsibility for solving any problem which may keep the patient from receiving service.

Maryland, Ellicott reported, has recently set up machinery for correlating its two State-operated chronic disease hospitals with other services. Both the hospitals and the integration program are operated by the State health department, he noted.

It will be the job of those directing the chronic illness program, Ellicott observed, to get cooperation: to increase understanding of the types of services available and the channels for referrals; to supply current lists of vacant nursing home beds to chronic disease and general hospitals; and to set up a consultation service for families and professional workers who need help in selecting the most appropriate facilities for various types of patients.

Allegheny County Restores "End of Line" Inmates

The hapless, hopeless, helpless "poorhouse" occupant can be transformed into a cheerful, conversant, and animated individual, the Allegheny County Institution District in Pennsylvania has found in its 8 years of experience with a physical restoration program at its Woodville and Mayview facilities for the indigent ill.

Too many county institutions practice debilitation rather than rehabilitation, declared Murray B. Ferder-

ber, M.D., assistant professor of medicine, University of Pittsburgh School of Medicine and consultant in physical medicine and rehabilitation to Allegheny County.

In 1946, he said, few medical personnel—institutional or private—felt that the county home candidate offered any chance for physical redemption. This "end of the line" concept did not reckon with the physical and emotional resurgence possible for even the aged under a regimen of good medical care, social services, and physical therapy, Ferderber indicated.

In calling for a revised attitude toward county institutions, Ferderber pointed out the reasons that may make admission to a public facility necessary. The course of productive convalescence may be too long and costly for private care; home care may take a wage earner out of circulation; the family may be unable to continue with the prescription; and the health of other family members might be impaired, he said.

Then and Now

Formerly upon admission to Allegheny County facilities, Ferderber related, the patient was "parked," given a routine examination, and the cursory "poorhouse" care, and left to exist socially as best he could.

Today, upon admission the physician follows the accepted routines of good medical care, basing his diagnosis on history, physical examination, and laboratory data, he said. The physician sets down definitive orders for the particular disability and pathology. The social service department integrates its information simultaneously.

The "team"—the physician, nurse, therapist, social worker, psychiatrist, and the orderly-attendant—meet at the patient's bedside to discuss the problems. The bedside meeting, Ferderber said, immediately dispels the patient's primary fear of neglect and constitutes the first step toward physical self-sufficiency.

The therapist and aide combine

efforts on indicated bed exercises and simple techniques that will prevent the deformity, bed sores, and other unnecessary results of excessive bed and chair fastness, he reported.

The next step, when the patient can be transported by wheelchair, he said, is the simply equipped therapeutic gymnasium for physical rehabilitation. The disabled engage in exercises commensurate with their ability, and in the course of this group participation the vacuous, stolid expressions of institutional apathy disappear, he said.

At least once monthly the rehabilitation board, composed of the staff physician in charge, social worker, rehabilitation technician, aide, and psychiatrist, meets to discuss the needs and disposition of the patients.

New Quarters

Physical restoration will be enhanced in a new county institution now under construction near Pittsburgh and expected to open in late 1956, Ferderber said. The institution will house about 2,200 patients and provide a well-equipped hospital for the needy ill with the exception of a surgical pavilion.

The institution district expects to follow its present procedure of calling in consultants and, when needed, of transferring the patient to the consultant's hospital for surgery, he said. The new building will provide simple egress for at least 1,100 ambulatory patients to park areas without the need for using steps and elevators. An auditorium built in four tiers will eliminate the use of elevators, ramps, and steps, and provide the patients with entertainment and recreation, he concluded.

Advocates Conservation Of Hospital Services

General hospitals will serve most effectively as powerhouses, not storehouses, in the treatment of protracted illness, C. Rufus Rorem, P.

tive director of the Hospital Council of Philadelphia, stated.

For some prolonged illnesses, he said, the hospital has served mainly as a dormitory with only occasional interludes requiring professional health services. He advocated conserving the use of hospital personnel, equipment, and buildings for professional health services.

Roem offered several other points for the comment, criticism, and action of professional and community groups in organizing health services for chronic illness.

Home care for chronic illness will achieve its destiny only when it is regarded as a professionally desirable procedure, not merely a "poor relation" of hospital inpatient service, he predicted. Most home care experiments administered by hospitals have developed from overcrowded conditions in their wards, Roem pointed out. He commented on the importance of recognizing that a person may be a "hospital patient" while receiving supervised care in his home.

Experimentation in improved care of prolonged illness need not wait upon new construction of facilities, Roem observed.

He pointed out, "If home care administered by visiting nurse societies can avoid the need for additional hospital beds, such ventures should be encouraged. If circuit rider medical services to homes for the aged can serve the health needs of most of the residents, the individuals, the hospitals, and the community will gain by the procedure. If existing homes for the aged and infirm can extend their recreational and personal services to elderly individuals living at home, they may reduce some of the illnesses attendant upon loneliness and boredom."

Roem also predicted that outpatient services for long-term illness will become increasingly important at hospitals, particularly for specialized procedures. They will conserve the professional energies of the attending physician.

The problem for individuals, pro-

fessional groups, institutions, and the general public is to develop health services in accord with changing patterns of homelife and community organization, Roem said. One thing seems clear, he concluded, there will need to be some changes made in the organization of health service, as well as in the sources and methods of financial support.

Uses of Epidemiology In Chronic Disease

Many epidemiological studies are "case series in search of a universe," said Philip E. Sartwell, M.D., M.P.H., professor of epidemiology, Johns Hopkins University, School of Hygiene and Public Health, in his discussion of the various approaches to the epidemiology of chronic disease.

Information is readily available on the characteristics of patients with a given illness, he said, but if the relationship of these characteristics to the disease is to be learned, their frequency in the population must be established. That is, a series of clinical histories must be related to the universe out of which they arose.

This, said Sartwell, is the task of the epidemiologist, and success may provide a clue to an unrecognized cause of the disease or even lead to a well-supported etiological hypothesis.

Source of Data

Pointing to the Federal census as the most obvious source of "denominator" information, Sartwell said, however, that knowledge of many chronic diseases already includes a rough idea of their distribution in reference to the data furnished by the census on age, sex, race, geographic distribution, and some other characteristics. Needed, he said, is an investigation of factors which are not as well known.

One approach to gathering these factors, he continued, is the type of community survey which after re-

peated house-to-house canvassing of all the families in 24 villages helped to identify the cause of pellagra in 1921. The objectives of the method are, at the same time, to find cases of a disease and to obtain denominator information on the population in which the cases appeared. Mass screening surveys are capable of furnishing similar information when appropriate information is secured on the population examined. Sartwell characterized this approach as too expensive and difficult to be used for rare illnesses or in any situation in which there is not already a hypothesis to be confirmed.

Refinement of the denominator data is possible when the population under study constitutes a defined group from whom specific information is routinely secured, such as employees of an industry or life insurance policyholders. Rates of prevalence, incidence, or mortality may be obtained which are specific for such factors as, for instance, occupation.

Random Sample

Instead of trying to learn the characteristics of the entire population, an alternative approach is to draw a random sample of the population, matched for age, sex, and race with the series of cases. Much more detailed information can be secured from such a control group than would be possible from the whole population. The frequency of the attribute in which we are interested can then be studied in the controls as compared with the cases. Sometimes, when the cases are a series of hospitalized patients, persons hospitalized with other diseases may serve as controls, although they are less satisfactory in some ways.

If an association is found by any of these methods between an environmental factor and the occurrence of a disease, it must be rechecked through repeated studies by independent methods. This may lead to the development of a more specific and useful hypothesis, the rejection of the whole idea, or to a completely

new avenue of inquiry. The long final step, from association to causation, is taken only after assembling information from all sources, demonstrating its consistency, excluding the possibility of indirect association, and if possible supporting the hypothesis with experimental laboratory evidence.

Urges Laboratories Develop Chronic Disease Tests

Just as in the past the public health laboratory has served the physician in his diagnosis and treatment of infectious diseases, it can serve him in the future in the control of chronic diseases, asserted Seward E. Miller, M.D., chief, Division of Special Health Services, Public Health Service.

The public health laboratory has an actual responsibility to help solve the main health problems of the day, he declared. Today, there is need and opportunity for further development of diagnostic tests, both general and specific, for the more than 50 chronic diseases to which our older population is susceptible, he said.

Of the three main services performed, research, diagnosis, and teaching and training, the major contribution of the public health laboratory is the development and application of diagnostic procedures, Miller commented. Equally important, he added, is the training of personnel in some of the newer diagnostic techniques as they are developed.

Clinical Diagnoses

Clinical diagnosis by laboratory examination has become an indispensable aid in medicine and surgery, he asserted. Present knowledge of the major chronic diseases, however, he pointed out, varies widely in the availability of diagnostic procedures.

Miller then reviewed the diagnostic status of arthritis, cancer, di-

abetes, and heart disease and discussed multiple screening and its relationship to clinical diagnosis.

Among the procedures needed, he said, is a test for rheumatoid arthritis. The National Institute of Arthritis and Metabolic Diseases, he reported, is now working on a serologic test which it is hoped will be as specific as the syphilis and diabetes diagnostic tests.

Another urgent need, Miller said, is a general test for the detection of cancer. The ideal test, he commented, would be applicable to most anatomic sites of the body, and could be easily and economically given to a large number of persons.

Not all of the responsibilities of the public health laboratory are associated with disease entities, Miller said in pointing out that there is a tremendous challenge in the problem of guidance for antibiotic therapy resulting from the introduction of antimicrobial agents.

Guidance, he maintained, should be the key word in the relationship with privately owned laboratories. The public health laboratory should not compete, but lead the way, training personnel and providing standardized solutions or reagents. Closer collaboration could facilitate solution of some of the diagnostic and therapeutic problems in chronic disease.

Insurance Study Affords Long View of Diseases

The value of a 1951 medical impairment study as a unique source of new data on the long-term effects of diseases and physical conditions was underscored by Edward A. Lew, actuary and statistician, and Herbert H. Marks, manager, medical statistics, of the Metropolitan Life Insurance Company.

This study, made under the auspices of the Society of Actuaries, included the experience of 27 large life insurance companies on 625,000 persons with specific medical impair-

ments to whom policies were issued at standard and substandard rates between 1935 and 1949 and who were traced to the policy anniversary in 1950.

Some 132 groups of impairments are included in the study. The average period of observation was slightly more than 6 years. The study results are presented in the form of ratios of actual deaths to the number of expected deaths if the mortality had been the same as that experienced by persons insured under standard ordinary policies during the same period.

Terming the study a "classical example of long-range followup studies," Lew and Marks enumerated the characteristics of the data:

1. The study group, drawn chiefly from white male adults in the middle to higher income brackets, represents a highly selected sample of the population. Their selection for ordinary life insurance presumes a good state of health.

2. Virtually all of the persons were medically examined. Frequently, supplementary information was obtained from the individual's physician.

3. The results of the medical examinations have been generally reported in terms of specific findings, not in diagnostic terms. Example: constant systolic murmur at the apex, *not* rheumatic heart disease.

4. The data represent the results of average medical care rather than care by selected specialists or clinical groups.

5. The survivorship record of the individuals included can be accurately evaluated by reference to the contemporaneous experience among all persons to whom life insurance was issued at standard premium rates during the period of the study.

6. The findings can be compared with information contained in earlier impairment studies of the kind.

Some New Facts

The conclusions can be useful to public health workers in evaluating

programs, estimating future case-loads, and in keeping the public informed about the outlook for persons with various medical impairments, Lew and Marks said. Such statistical studies may be expected to shed light on the natural history of chronic diseases, they added.

Selected findings which bear on traditional public health problems were reported. Among them, briefly stated here, were these:

Pulmonary tuberculosis. Underweights experienced mortality no higher, and in some instances, lower than persons of average or above average weight. The extra risk of death from the degenerative diseases of later life associated with even a slight degree of overweight currently overshadows the extra risk of death from tuberculosis and other respiratory diseases in the long-range picture. The need for continuous medical supervision of persons with a history of active tuberculosis is indicated by the excess mortality from the disease in this experience.

Coresidence with tuberculosis. Contacts are subject to an appreciable extra risk of acquiring the disease and might, therefore, benefit from periodic medical checkups.

Rheumatic fever. Relatively high mortality among the cases under 30 at time of policy issue points up the sizable risk of its recurrence, even though a considerable time may have elapsed since the last attack and no evidence of heart damage is found on examination. Mortality was even higher among cases with a history of rheumatic and streptococcal infection who were found to have a systolic murmur over the apex of the heart and especially so when the heart was enlarged.

Diseases of the cardiovascular system. Among persons with two or more close relatives under age 60 with heart or related disorders, the death rate was significantly higher than normal, primarily because they, too, experienced excess mortality from these cardiovascular conditions.

Polio myelitis. For those issued

standard insurance, despite the crippling effect of the disease, the mortality was about the same as for standard life insurance risks. Among the cases with more serious degrees of crippling, who were limited to substandard insurance, the mortality was about one and one-half times the expected.

Syphilis. The results in the carefully selected cases accepted for life insurance indicated that adequate treatment of syphilis by earlier methods (heavy metals) was apparently successful for many.

Maternal hygiene. Women who have had a child delivered by cesarean section run an extra risk in subsequent pregnancies, but the operation itself has no adverse effects on the longevity of the mother.

Mental disorders. Suicide accounted for a major portion of the excess mortality among persons with a history of neurasthenia, psychoneurosis, or of psychosis. An above-normal suicide rate was recorded also in those who reported a history of insanity in two or more close relatives under age 60.

Insecticides and Pesticides . . .

The subject of DDT toxicity and the potential hazards involved in the use of the cholinesterase-inhibitor group are reviewed. The role of pesticides in agriculture and the Federal regulations for testing and controlling pesticides prior to marketing also are discussed.

Cholinesterase-Inhibitor Group Reviewed

A great deal of confusion and lack of understanding exist concerning the potential hazards of organic phosphates of the cholinesterase-inhibitor group such as parathion, malathion, Diazinon, Shradan, and Systox, when they are used as pesticides, declared L. W. Hazleton, Ph.D., president, Hazleton Laboratories, Falls Church, Va., in spite of the fact that rarely has so much been known about a class of chemicals and its individual members before they are put to constructive use.

Some of these materials are relatively nontoxic; others are acutely hazardous, Hazleton said. All are toxic following oral administration, dermal application, or inhalation of particulate matter.

The danger to the user or to the general public is no greater than the hazards from other commonly used industrial and agricultural chemicals, Hazleton stated. Danger is practically nonexistent, he said, because of the nonresidual nature of the chemicals, the intensive research made by industry, and the vigilance of the authorities regulating their manufacture and use.

Both Federal and State authorities require manufacturers to make extensive toxicological studies on each pesticide before it can be put on the market, he said.

Hazards to Workers

Persons engaged in the manufacture and formulation of organic phosphate pesticides and those who handle them in concentrated form are in danger of toxicity and should be protected from exposure, Hazle-

ton warned. However, industrial hygiene techniques have practically eliminated hazards under these conditions, he said.

Individuals continuously exposed to these chemicals should have periodic checks on cholinesterase activity; those who complain of symptoms which might be associated with exposure to pesticides should be referred to a physician who is familiar with pesticide poisoning.

Although information regarding safe handling of the cholinesterase-inhibiting pesticides is available, occasional accidents occur because of failure to follow directions and carelessness in handling the material. Fortunately, recovery from both acute and subacute toxicity is complete, with no residual storage or pathology.

Pesticides Must Be Tested Before Approval for Use

Pesticides can no longer be placed on the market without first being thoroughly tested, reported Justus C. Ward, M.S., in charge of the Pharmacological and Rodenticide Unit, Agricultural Research Service, United States Department of Agriculture.

The Insecticide Acts

The Insecticide Act of 1910, which until 1947 was the principal Federal statute dealing with pesticides, related only to performance and purity, Ward continued. However, it became apparent that certain classes of pesticides which were not included in the 1910 law also needed control, and that many other features of poison handling were highly important, he said. This was particularly true, he said, from 1935 on, when new and spectacular insect, weed, and rodent killers presented problems for which there were no answers.

In June 1947, Ward said, the Federal Insecticide, Fungicide, and Rodenticide Act became law, and indis-

criminate introduction of new and strange poisons into interstate commerce was immediately halted. This law required registration and clear labeling of poisons so that the user would know upon reading the danger involved in handling them, would know how to avoid injury, and, also, would know how to use the material to avoid destroying beneficial forms of life.

In addition, the law allowed controls over dosages of the pesticide that "would guarantee that the residues left on food crops would be within acceptable limits."

The 1947 act authorizes the Department of Agriculture, which is responsible for enforcement of the law, to consult on hazard problems of new poisons with the Public Health Service and evaluation of food residues with the Food and Drug Administration.

Extent of Testing Varies

There are many complex tests to be performed before a research chemical becomes a pesticide, Ward stated. When a use for a chemical has been discovered, the commercial agency which will exploit it must make a minimum toxicological evaluation to determine its acute oral toxicity, its skin absorbability, and its inhalation hazard.

The use for which the chemical is intended will then determine whether further study is needed, and how much. For example, if a chemical to be used in agriculture presents no unusual hazards to the person using it and the precautionary labeling has been approved by the Public Health Service, it could be approved for use as an insecticide on nonfood crops. Long-term pharmacological data and adequate chemical residue analysis would be necessary before it could be used on food crops.

Household Pesticides

Household pesticides which require protective clothing and special equipment should be used only by professional pest control specialists,

the speaker said. Sprays for use in the home require the collection of extensive data on oral toxicity, skin absorption, and inhalation hazard. If the product is to be used in any way so that it will touch the skin, studies on skin irritation or sensitization must be done. If it is to be used as an aerosol or hand spray, repeated inhalation tests are necessary.

Protection Increasing

The law also permits the Secretary of Agriculture to cancel full registration. This action must be followed immediately, however, by the issuance of a registration under protest. This is accomplished by a letter to the manufacturer detailing why the action was taken. Such a procedure, Ward stated, permits prompt action in notifying a manufacturer that unfavorable use experience has indicated need for curtailing distribution of his product.

A great deal of progress has been made in the control of poisons since the act of 1947 was passed, the speaker concluded, and as the laws are amended controls become more precise. "The public is demanding increasing protection against insidious chemical agents, whether they may be smog, car gas, industrial fumes, strong drugs, household chemicals, intentional food additives, or pesticides," Ward stated.

Toxicologist Reviews DDT Intoxication

DDT is a safe material for men to use, Wayland J. Hayes, M.D., Ph.D., chief, Toxicology Section, Technology Branch, Communicable Disease Center, Public Health Service, Savannah, Ga., reported in reviewing present knowledge about DDT intoxication.

Abundant evidence is now available about human exposure to DDT, and such quantitative information should help satisfy any reasonable doubts about the safety of this chlor-

inated hydrocarbon insecticide, he said. Cautioning against alarm because of the need for additional research, he stated that human beings can withstand much greater exposure and storage of DDT than are now prevalent.

Today's Knowledge

"The greatest recent advances in our knowledge of DDT are those which define the current exposure and the magnitude of tolerable dosages involving this compound," Hayes stated.

Because a greater tonnage of DDT is produced than any other insecticide—because it occurs as residues in food—and because it is stored in human tissue, interest in the material, already the subject of advanced chemical analysis, continues, he commented. Much remains to be learned about its toxicology and pharmacology, and about its basic mode of action.

Careful studies with extensive occupational exposure are proving the safety of the material, he added, in calling attention to these observations: In spite of the tremendous tonnage of the compound being used, the total number of reported cases of dermatitis from DDT is very small; the number of accidents has been very small; there is no well-described case of fatal, uncomplicated DDT poisoning; except in severe cases, recovery from mild poisoning has always been well advanced or complete in 24 hours; no instance of chronic DDT poisoning in man has been confirmed; and dermal exposure under conditions of actual use has not been sufficient to produce systemic poisoning.

More occupational disease has been caused by the solvents in DDT formulations than by the compound itself, Hayes pointed out. A number of deaths have been reported following the ingestion of DDT solutions, which are obviously dangerous to drink. Experiments with animals have revealed that digestible animal and vegetable oils enhance the toxicity of large doses of DDT. Kero-

sene, the most common solvent for this compound, has a considerable toxicity for man, a fact not fully appreciated.

The suggestion that DDT is the direct cause of a viruslike disease and of a psychoneurotic syndrome, as well as a contributing cause of poliomyelitis, hepatitis, cardiovascular disease, cancer, and a formidable array of animal diseases, finds no support in animal experiments or in human morbidity or mortality statistics, he remarked.

Our Daily Diet

Fatty foods, or foods cooked in fat, tend to contain more DDT than other foods, but there is no indication that the amount of DDT occurring in our diet or stored in our fat is injurious, Hayes assured. Three well-balanced meals a day yield the equivalent of a dosage of 0.0026 milligram per kilogram per day, which may be compared with that of 0.5 mg./kg./day being taken currently without injury by volunteers, he said.

Hayes reported other findings relating to the effect of DDT on man. Some of these are summarized below:

Oral dosages of 285 mg./kg. have been taken without fatal result. But these and even smaller dosages lead to prompt vomiting so that the amount actually retained cannot be accurately determined.

Still unknown is the least dosage which, when repeated daily, will lead to illness.

No quantitative estimate can be given of the dermal toxicity of DDT to man. Many investigators have found it impossible to determine the medial dermal lethal dose (LD₅₀) of DDT because the material was simply not toxic enough. All agree the dermal LD₅₀ of undissolved DDT is extremely high—400,000 mg./kg., or greater.

DDT is broken down by the body. Two of the products, both formed by man, have been identified: DDA, the acetic acid derivative of DDT, is excreted in the urine; and DDE, the

dehydrochlorinated derivative, is stored in the fat. Since it is indicated that significant dosage levels of DDT can be quantitatively related to the excretion of DDA in the urine, it should now be possible to measure objectively the exposure of workers, some of whom have been constantly engaged in the manufacture of DDT ever since its introduction to general use in this country in 1946.

Pesticides Save Lives, Aid in Food Production

Without pesticides, the quantity and quality of our food, feed, and fiber would be drastically lowered, according to H. L. Haller, Ph.D., assistant director of Crops Research, Agricultural Research Service, United States Department of Agriculture. The use of pesticides to control insects saves millions of lives and reduces sickness and misery, he maintained.

Since the introduction of new pesticides, average per acre production of many crops has increased, in some cases by as much as 60 to 70 percent, he reported. Although not entirely due to their use, evidence shows that pesticides are a major factor in increasing the production of onions, potatoes, lima beans, and tomatoes, he commented.

Haller reported that with one-third fewer workers and about the same total cropland as in 1919, agriculture is now supplying a population 53 percent larger and producing better quality foods. However, he asserted, this effectiveness is only comparative and our margin of safety is thin. He pointed out that the losses still caused by crop and animal diseases, by parasites, insects, and weeds have been conservatively estimated at about \$9.5 billion a year in a recent survey.

Food and Health

Emphasizing that good public health is directly related to good

nutrition and not merely the prevention of infection, Haller went on to show that high-quality diets depend on scientific attacks against the fungi, bacteria, viruses, and nematodes which interfere with the productivity and quality of grain, fruits, timber, fiber and other crops.

In the war against weeds, he said that scientists are always aware that an average ragweed plant takes three times as much water from the soil as corn, that mesquite has made worthless 60 million acres of grazing land, that halogeton kills sheep, and that Canada thistle, Johnson grass, field bindweed and others choke and ruin crops. The insect enemies, which destroy crops and contribute to soil erosion as well as transmit diseases to man, he said, add up to an army of more than 700.

"The situation remains nip and tuck," he warned. "Competent agricultural scientists have pointed out time and time again that even a statistically small letup in the fight

could very well set back our agriculture by many years."

Current Research

Considerable research is needed, he said, to find effective controls for organisms that infest the soil. Tests with some of the new organic compounds have reduced infestations and brought striking increases in crop yields, he reported.

He cited the need for improved grasslands and for development of new herbicides, botanical pesticides, and antibiotics to control bacterial diseases of plants. All effects of chemical agents on quality of produce must be studied thoroughly before widespread use.

The control of insect vectors of diseases has been greatly aided by insecticides, but new compounds are needed because of the resistance to DDT developed by insects, Haller stated. As many as 2,000 new pesticidal compounds are formulated and evaluated every year, he said.

status. They were selected, said Dillard and her associates, so that each school child had at home a pre-school sibling of the same sex and not more than 2½ years younger. Observations were repeated periodically on each child until the pre-school sibling had completed at least one school grade. Of the 66 pairs who began, 54 completed the study.

Sibling Comparison

Although the minimum deficiency symptoms were noted in about the same proportion of older and younger children, relatively few sibling pairs, said Dillard and her co-workers, showed the same symptoms at the same time, except in the case of long-bone deformities. They said that slightly more than 50 percent of the 56 children showing this condition were sibling pairs.

An apparent improvement in the physical condition of most of the children who received both examinations was indicated, according to Dillard and her colleagues, by a decrease in the observed number of clinical symptoms and by an increase in the number of children whose general appearance was considered good.

The dental caries rate of the children studied was high, but comparable to that reported in other studies on children of similar ages from areas where water supplies contained approximately the same amount of fluoride, 0.5 p.p.m. The average number of teeth that were decayed or filled increased from 2.9 to 5.4 for boys and from 4.3 to 6.0 for girls between the first and final examinations, Dillard and her associates reported.

Weight Range

They said that over two-thirds of the weights recorded for all children were within the range set by the usually accepted standards for height and age. More weights below 10 percent of the standard were recorded than above the standard. However, since the deviation from

Nutrition for School Children . . .

When children in Iowa are not getting enough milk, fruits, and vegetables, as reported in one study, or when only 35 percent of all school children in the country have good diets, as reported in another study, perhaps more emphasis is needed on surveys of opportunities for education in good nutrition.

Children's Nutritional Status Studied in Nashville

Only minimal symptoms of possible nutritional deficiency were found in a 3-year study of the food intakes and nutritional status of Negro children in Nashville and Davidson County, Tenn.

A preliminary report on the study was made by Norma P. Dillard, M.A.,

nutrition analyst, and Verz Goddard, Ph.D., both of the Human Nutrition Branch, U. S. Department of Agriculture, Erna B. Jones, M.S., head, department of home management at Tennessee Agricultural and Industrial State University, and Natalie M. Tanner, M.D., of Detroit.

The project, completed in 1952, reported findings for 132 children, 66 pairs of siblings, chosen from families of comparable socioeconomic

standard was greater for the overweight (the highest 44 percent above the standard as compared with a low of 25 percent for the underweight), the average weights fall very close to the standard.

Similarities in the findings for the sibling pairs were most obvious in the data resulting from the blood analyses made twice during the study, said Dillard and her co-workers. Blood serum levels of protein, ascorbic acid, and vitamin A were adequate for the majority of children, but the hemoglobin values were far below those reported by other investigators.

The minimal signs of nutritional deficiency most frequently observed were changes in the mouth, skin, skeletal structure, and teeth, according to Dillard and her colleagues. They said that many of the symptoms noted at the beginning of the study had apparently disappeared when the children were reexamined at its close.

Classroom Good Place To Teach Nutrition

In serving lunches schools have an excellent opportunity to teach by example, as well as by classroom instruction, how to select an adequate and nutritious diet, stated Austin E. Hill, M.D., M.P.H., director of public school health services, Houston, Tex.

He suggested that schools sell only types of candy that contain ingredients which will supply needed nutrients, such as milk, egg whites, and peanuts or peanut butter, to aid in providing the child's daily protein requirement.

Pointing out the dangers of inadequate nutrition, he said that in this country only 35 percent of all school children have good diets. Poor nutrition, he maintained, is not solely an economic factor because many families in the lower income levels are well fed. The problem is not only one of educating children,

Number of calories per day needed by children, according to age ¹

Age (years)	Calories required (Girls and boys)	Age (years)	Calories required	
			Girls	Boys ²
10-12 months.....	1,000	10	2,000	2,000

parents, and teachers as to what constitutes a proper diet, Hill continued, but is concerned with application of the knowledge.

Hill defined the type of meals best adapted to supplying children with the daily nutrition requirements. In the table he gives the approximate daily caloric intake needed by children according to age.

He also compared the protein and caloric needs of school children with that of certain adults. For instance, he said a child between 7 and 9 years old needs as much food as the average middle-aged woman; a boy of 15 needs more food than his male teacher or athletic coach; and a 15-year-old girl needs the same amount of food as a pregnant woman. Most parents fail to understand that almost all school children actually need more food than their parents, said Hill.

Protein Essential

Each day should begin with a good breakfast, high in protein content to help maintain a more constant blood level, Hill suggested. Children should eat at least three foods rich in protein at each meal to assure the full recommended daily protein consumption by bedtime.

"Protein is the most important

diet constituent, and it is the most prevalent deficiency in the diet of school children," Hill declared. A steady loss of protein occurs in the body which must be replaced by a constant and adequate daily intake because proteins are not stored by the body as are carbohydrates and fats, he explained.

School Lunchroom Survey Reveals Deficiencies

Periodic sanitary inspection of school lunchrooms and periodic review of the way the lunch programs are used for educational purposes were recommended by Charles C. Wilson, M.D., and Eric W. Mood, both of Yale University, on the basis of data collected in a 1954 survey of 795 schools. Dr. Wilson is professor of education and public health, and Mood is lecturer in public health.

These activities, preferably carried out cooperatively by school and health department personnel, will point the way for further specialized investigation and provide the bases for improved school sanitation and health education programs, they declared.

The following survey findings were reported.

Sanitation Practices

Almost all the schools (731) have an adequate supply of running hot water, and 605 obtain their water from a public water source.

Forty-six percent of the schools have an installed dishwashing machine, and 19 percent, 3-compartment sinks, but 31 percent use 1- or 2-compartment sinks or dishpans.

To the question, "Are food displays covered or shielded by glass or plastic?" only 58 percent answered affirmatively.

Although only 2 schools specified that they did not use mechanical refrigeration, only 462 reported a thermometer in each refrigerator.

Almost half the schools (358) have an insect control problem, and approximately 1 out of every 3 (259) has a rodent control problem.

Health Education

A majority of the schools (448) require pupils to wash their hands with soap and water before lunch, but 274 do not require this procedure.

Less than half (308) of the schools assign pupils to observe and report on food handling practices, and only about half (304) assign pupils to observe and report on pupil lunchroom practices.

In 50 of the schools, pupils assist in the preparation of food; in 368, they help in serving food; and in 524, they assist in cleaning up the lunchroom. In 518 schools, the children are instructed in sanitary procedures and reasons for the instruction are explained.

Sanitation in public eating places is studied in 64 schools "intensively"; in 543 "casually"; and in 104 "not at all."

Survey Methods

In this survey, data were collected by two methods, Wilson and Mood specified. For 646 schools, questionnaires were filled out by members of the American School Health Association. For 149 schools, interviews were conducted by graduate students

in public health and by health department sanitarians. Included in the survey sample, they stated, were elementary, junior high, and senior high schools in towns and cities of all sizes in all geographic areas of the Nation.

The increasing scope of school lunch programs was one factor stimulating the survey, they indicated. They estimated, from Department of Agriculture figures on the National School Lunch Program, that 1 out of every 3 school children eats his noon meal in the school lunchroom. Another factor was the occurrence of foodborne disease outbreaks attributed to food and drink served in the school lunchroom.

School Children in Iowa Lack Calcium, Vitamin C

Even in seemingly well-fed Iowa, there are nutrition problems among school-age children which merit serious attention, according to the findings of a 5-year statewide research program.

Ercel S. Eppright, Ph.D., head of the department of food and nutrition, Iowa State College, reported on the study. The study, she noted, has been probing the tie between what children eat and their general state of nutrition.

Lack of sufficient calcium and vitamin C for all children was so frequent, Eppright said, that the problem might well be tackled in a statewide nutrition education program. For girls 12 years of age and older, lack of sufficient iron was a frequent finding.

Iowa school children tend to follow the eating patterns previously observed for their parents, she stated. They are eating well of such foods as meat, potatoes, fats, and bread and other cereals, but they are not getting enough milk, fruits, and vegetables, the study revealed.

Eppright reported that the mean nutritive value of the diets of the children (except girls over age 12

years) was close to or better than the recommended daily allowances of the National Research Council. This finding, however, could be termed "false security," she noted, for "there is a fairly large proportion of children whose diets are not well-fortified by certain nutrients."

According to analysis of finger-tip blood samples, vitamin C nutrition was found to be less than optimum for many children and actually poor for approximately one-fourth, she specified. A lack of carotene-rich fruits and vegetables in the diets of many children also produced results evident on analysis of blood samples.

Teen-Age Girls

Most conspicuous for poor diets were the teen-age girls, Eppright emphasized. More than half had diets which appeared to be grossly inadequate. She pointed out that this is a particularly critical group since it concerns the well-being of the future generation.

Among the teen-agers, overweight girls were conspicuous for their poor diets, she said, suggesting that concern about overweight should focus attention on the inadequately nourished, overweight teen-ager.

Concerning physical development, Eppright reported that the children appear to be growing satisfactorily according to standards of physical fitness. Children with liberal diets tend to be slightly taller, heavier, and larger in leg girth than children whose diets are somewhat below the recommended dietary allowances, she noted.

The study, she said, has pointed to the importance of keeping systematic records of height and weight of children. She recommended that schools follow such a procedure as part of their school health program.

The most conspicuous physical defect found on clinical and dental examination, she added, was poor teeth. More information is needed about the impact of the nutrition of children on the condition of their teeth, she declared.

Use of Exhibits, Publications . . .

Prenatal pamphlets, workable "suitcase" exhibits for children, modern format for medical and public health publications, and the need for coordinated efforts of various agencies in health education programs are discussed.

Prenatal Pamphlet Series May Benefit Mothers

A series of prenatal pamphlets was found in a recent study in New Orleans, La., to have some effect on the knowledge and attitudes of expectant mothers, according to Loyd W. Rowland, Ph.D., director, Louisiana Association for Mental Health, and Joseph F. Follettie, M.S., lecturer in social research, Tulane University Graduate School of Social Work.

This conclusion was based on the responses of 51 mothers who had received the series and a control group of 95 mothers to 55 questions relating directly to the series materials. The showing made by the two groups favored the experimental group for 39 questions and the control group for 15, they stated, pointing out that the difference between 39 and the number of questions for which the responses would be expected to favor each group, 27, is significant at the 0.001 level. Only 2 of the questions, taken individually, showed a statistically significant difference at the 0.05 level, they added.

They reported that the two groups were selected from among 436 mothers who had had first babies in private hospitals in the city during a 2-month period. The groups were fairly well equated as to amount of reading other than the series materials, employment of the father, and income, they said.

They suggested, however, that the following procedures might yield a more definitive study of the prenatal materials: interviewing the mothers immediately before the birth of their

child; selecting experimental and control groups from the same statistical universe; selecting sample groups racially and socioeconomically representative of the statistical universe from which they are drawn; and using professional interviewers.

Concerning the first suggestion, Rowland and Follettie pointed out that the interval of time transpiring between the birth of the child and the time of the study may have decreased the chances of getting favorable results. There is a medical tradition that regardless of anxieties beforehand and the unpleasantness of the birth process there is a conscious effort on the part of the mother to forget all of it, they explained.

Acceptance by Authorities

Noting the difficulty of measuring knowledge of learned material and the even greater difficulty of measuring attitudes, Rowland and Follettie suggested two criteria that they believe are fairly reliable for judging educational materials: the acceptance of the material by authorities in the field and the popularity of the material with those expected to use it.

Applying the first of these criteria to the prenatal pamphlets, Rowland and Follettie asked 100 physicians who distributed the materials to their patients for their opinion of the materials. Forty-five responded, all favorably, the responses ranging from a simple "good" or "continue" to lengthy commendations, they said.

Efforts to determine the effectiveness of what is being done in the

health education field should not be relaxed, they declared. Each evaluation study, they said, helps to develop standards and thus benefits the whole health education movement.

Modern Formats Attract Responsive Readers

Pamphlets and magazines which aim to inform busy members of the medical and public health professions should be as smartly designed, as well written, and as attractively illustrated as the sales pamphlets, literary and picture magazines, and other printed matter which compete for attention. Publication figures and reader surveys confirm this, according to Russell W. Cumley, Ph.D., director of publications at the University of Texas M. D. Anderson Hospital and Tumor Institute, and executive editor of *The Cancer Bulletin*.

A dynamically designed and illustrated pharmaceutical publication stimulated an unprecedented increase in sales of the manufacturer's products, he said of a journal with which he was previously associated. Accordingly, it was decided to publish *The Cancer Bulletin* in contemporary format, assuming that this would attract more readers.

Originally distributed to 7,500 Texas physicians, within one year the circulation jumped to 100,000, as requests for copies were received from physicians and cancer control agencies in other parts of the United States and in many foreign countries, Cumley stated. Regional reader surveys indicated that 50 to 90 percent responded, an extremely high percentage. Nearly 90 percent of the responding physicians indicated that the periodical aided them in their practice.

Articles usually have a large and provocative illustration on the first page, Cumley said. This draws attention to the title. Primarily designed to induce further reading,

the title does not necessarily indicate the content of the article. A subtitle takes over this function. If no subtitle is used, the title itself must fill this need and lead the reader to the first paragraph. This paragraph presents the general substance of the article and should assure that continued reading will be beneficial. The remainder of the article proceeds swiftly to present its case with as few words as possible.

Journalistic presentation throughout does not compromise scientific integrity and, when the last paragraph is reached, Cumley stressed that the reader should be left with a feeling that he has benefited by the reading.

Health Museum Designs

3-D Suitcase Exhibits

Suitcase exhibits with three-dimensional models are being used in the health education area served by the Cleveland Health Museum, Cleveland, Ohio. Unique in school health education, and still experimental, the series is proving to be a fascinating and practical way of having children visualize health concepts, according to the museum's curator of education, Winfield G. Doyle, Ed.D.

Children like exhibits they can work themselves, Doyle said. A child can touch and work any of the 14 exhibits in the museum's current series on good health habits and the science of the body. The exhibits were displayed at the annual APHA meeting.

The series has been developed for classroom use at many grade levels. Although designed originally to meet local needs, it can be expanded to include more specialized topics. Standard-sized suitcases hold most of the exhibits. Few weigh more than 50 pounds apiece. All come equipped with leather carrying handles. None is too big for a teacher to handle. All displays are large enough to be seen in the average classroom.

Instruction aids, such as charts

and diagrams, are part of the exhibits. A master magnetic tape has been prepared for each suitcase, describing the exhibit in detail, and giving teachers pointers on what to stress at different grade levels as well as suggestions for coordinating class projects. The teacher can review the subject matter on the tape before taking the exhibit into the classroom.

The Visual Appeal

Some of the exhibits are designed for the youngest pupil to understand, Doyle said. Captions are simple and interest-provoking. All exhibits use cheerful color combinations. Children are given a chance to eat unfamiliar foods and to correct poor eating habits at "tasting parties," in connection with one exhibit, "Foods Can Be Fun."

Some of the exhibits rely on swinging or removable panels to unfold a complex idea or to highlight the difference between desirable and undesirable habits. "Rest and Sleep" uses a window shade to suggest the familiar act of pulling down the shade in a child's bedroom before he retires.

Some of the models of the organs of the body are completely dissectible. The ear model in "How We Hear" comes apart so that it can be used for discussion of the structure of the outer, middle, and inner ears.

When a button is pushed in the posture exhibit "Straight and Tall," a boy standing straight like an "I" slumps into curves like an "S." The exhibit "Teeth Are To Keep" has models of a molar, an articulated denture, and a few common dental instruments, such as a mouth mirror and saliva extractor.

The eye and ear exhibits also aid the school or public health nurse in her screening and testing. In "Why We Need Glasses," nearsightedness, farsightedness, astigmatism, and double vision are shown. Diagrams showing these defects are on one panel, while on the right, the same scene has been photographed as it would appear to persons having these defects. Plastic slides hang on pins over the eyeballs to show

how the defects are corrected with lenses. A dissectible eyeball is included along with a Snellen chart, a series of color cards for testing color vision, and a near-vision chart.

Health Education Programs Need Coordinated Effort

All persons in the education, public health, and welfare fields must work together if health education programs are to be complete, declared Dora A. Hicks, Ed.D., chairman, professional health education, University of Florida. Cooperative and coordinated planning techniques are needed to prevent duplication of some procedures that are necessary to solve the health problems of students and to avoid omission of others, she said.

A technique for evaluating school health programs which will eliminate subjective judgment as far as possible and will show results of health education in terms of actions and accomplishments has been needed for some time, Hicks continued. Periodic systematic examination of health programs will yield information that will be helpful in future planning, she stated.

Hicks described the development of a technique for self-evaluation of the entire school health program. This technique, she said, is apparently more objective and more adequate than any that has been reported so far and should serve as a guide for evaluating any school health program. Development of the technique included a review of the literature; establishment of a list of accepted standards, policies, and procedures for adequate school health programs; construction of a survey form; and preparation, comparison, and evaluation of the data.

Sources of Standards

A number of sources related to school and community health were consulted in developing the evaluation technique, Hicks said. Among these were reports and studies by

professional organizations; surveys of health practices; studies on legislation and State regulations; health education textbooks; group reports and studies on special problems, such as organization, administration, and supervision; and conference reports.

Hicks stated that a full report of the development and application of the self-evaluation technique of school health programs and the results obtained is contained in an unpublished study, "Evaluation of an Inservice Program for Improvement of School Health Education."

Under carefully controlled conditions, this mixture was divided into samples in test tubes, quick frozen, and after packing in dry ice, was sent to the pilot laboratories. At a given time the next day, when all samples could be presumed to have been delivered, a standard plate count was performed adhering to the Standard Methods for the Examination of Dairy Products with one exception, they related.

Results on the first 50 split milk samples, they reported, were as follows: Laboratory A agreed within 10 percent with the control laboratory on 81 percent of 31 specimens tested; laboratory B, on 64 percent of 50 specimens tested; laboratory C, on 70 percent of 50 specimens tested. These laboratories could reproduce the results of the control laboratory within 10 percent 73 percent of the time, within 15 percent, 83 percent of the time, and within 20 percent, 93 percent of the time on the average.

Tests with a second group of 25 split milk samples did not yield any greatly improved results, although modifications to improve the agreement between laboratories were made, they reported.

Food and Milk Sanitation . . .

Although progress was reported in restaurant sanitation, there remains a job to be done, especially in educating restaurant workers. Take-out foods are receiving increased attention. Improvements in milk sanitation equipment and methods were discussed and Missouri reported on its experience with an approval program for local milk laboratories.

Local Milk Laboratory Approval Program

Experience in trying to organize a local milk laboratory approval program in Missouri has shown that a 20-percent deviation from the State laboratory findings would be a practical standard, according to Irma C. Adams, B.S., director, bureau of laboratories, and William J. Beck, M.S., bacteriologist, Missouri Department of Public Health and Welfare.

The organization of the approval program included development of a method for performance of tests on split milk samples by the local and State laboratories for control purposes, they related. It was found that the standard of agreement—within 10 percent deviation—between State and local laboratories, as had been previously suggested, would be impossible at this time for the laboratories in Missouri, they declared.

Program Preparation

The first step taken to develop the Missouri approval program was to

give a series of workshops on the actual techniques and tests performed, they related. As it was impossible for all the technicians to attend the workshops in 1950 and 1951, during 1952 and 1953 local laboratories were visited by State laboratory personnel and surveyed, using the Public Health Service form, on equipment and methodology, they explained.

This second step revealed that only 10 of 22 laboratories visited had satisfactory compliance. The largest deviations found through the survey forms, next to keeping records, were in the apparatus used, plating techniques, and variations of incubation temperatures, they reported.

Split Milk Samples

The third step in the laboratory approval program was the development of a plan for utilizing split milk samples, Adams and Beck reported. Two or three of a given amount of known organisms, *Escherichia coli*, *Micrococcus pyogenes aureus*, *Streptococcus liquefaciens*, and *Sarcina lutea*, were added to cold sterile skim milk, they said.

Food and Beverage Council Objectives Explained

Existing ordinances and codes governing sanitation requirements in public and private eating establishments should be reevaluated in the light of present-day conditions and new knowledge, stated Henry F. Vaughan, Dr.P.H., dean, University of Michigan School of Public Health, and president, National Sanitation Foundation, in discussing the food protection program of the National Food and Beverage Council.

The National Food and Beverage Council was organized in 1953, Vaughan reported, under the joint auspices of the National Restaurant Association, the American Hotel Association, the Public Health Service, the National Sanitation

Foundation, and State and local health services. The council's purpose is "to encourage people to know the value of and to demand quality food, well prepared, served in a clean and sanitary manner in clean, pleasant surroundings, whether at home or any other place where food and beverages are served," he said.

Sanitation Pattern

Vaughan summarized the council's activities as follows:

1. Developing of voluntary and coordinated leadership among health authorities, industry representatives, other groups, and individual citizens.
2. Obtaining endorsement and support from food and beverage associations, individual companies, and members of the public.
3. Developing educational material and instruction aids to be used at all educational levels.
4. Forming a permanent staff to launch and keep the program going in all of its phases.
5. Establishing pilot programs in representative communities and working out details of activating communitywide educational programs with State and local leadership.

Vaughan suggested the issuance of a guide or manual which would combine the best features of existing food and beverage service regulations and provide a uniform sanitation code for communities and industry to follow. He felt such a manual should be prepared through the joint efforts of the leading food and beverage industries and Federal and local public health organizations. Continued research, he said, should provide up-to-date technical data to keep the food protection program effective and nationally acceptable.

Notes Equipment Advances In the Dairy Industry

Reviewing methods and equipment which have been introduced into the dairy industry during the

past 10 to 15 years, H. L. Thomasson, executive secretary for the International Association of Milk and Food Sanitarians, Inc., named the bulk farm cooling tank as probably one of the outstanding developments.

Significant features of the bulk farm cooling tank, Thomasson noted, are fast cooling, ease of cleaning, elimination of the use of heavy cans, and minimum exposure of the milk to contamination. The use of this tank also eliminates the need for can washers in the pasteurization plant and for the handling of empty return cans, he said.

Other developments that Thomasson considered noteworthy include the following: the farm tank pickup truck; cleaned-in-place pipelines; bulk milk dispensers; improvement of dairy herds through artificial insemination; the Ring test for brucellosis; vacreators; high-temperature, short-time, continuous flow pasteurizers; automatic feeders for the addition of vitamins; improved cleaning compounds; the formation of the 3A sanitary standards group; and the use of paper containers in the distribution of milk.

Although bulk milk dispensing is not new, this type of milk distribution has been greatly improved, Thomasson specified. Pointing out that the filling of cans at the pasteurization plant has been one of the knottiest of sanitation problems, he reported the recent development of an automatic can filler that operates in the same manner as a glass bottle filler and thus eliminates the need for filling cans manually.

New Fortification Method

Thomasson also reported that a new method has been devised for continuous flow fortification of milk with vitamin additives. The device is the first with design and operating principles acceptable to sanitarians, he stated. He explained that with batch fortification, the sanitarian has little opportunity to check the actual performance of fortification unless he happens to be present during the process. With the new

method, the sanitarian has an opportunity to see whether fortification is being done in the proper manner since the unit operates continuously during pasteurization.

The 3A sanitary standards group, formed in 1941, is helping to eliminate what once was a major problem in the dairy industry, that is, the necessity for manufacturing equipment to meet a variety of health requirements, Thomasson indicated. This group, composed of 3 committees representing various organizations, has established 16 standards and 3 revisions covering types of materials, finish, fabrication, construction, and other design features for various kinds of equipment, he stated. Although progress is sometimes slow, eventually all dairy equipment will be covered by the standards, he declared.

Remarking that research on methods and equipment is going on all the time, Thomasson mentioned sonic pasteurization (destroying bacteria by sound waves) and radiation sterilization (sterilization by light waves, infrared, or similar means) as among the areas being studied today.

Sanitation Problem Seen In Take-Out Foods

Serve-yourself freezers and rotisseries provide marketing conveniences but pose another problem—that of sanitation of take-out foods, according to one report.

The report was made by Charles L. Senn, director of the sanitation bureau of the Los Angeles City Health Department, and Col. Paul P. Logan, director of research, National Restaurant Association. They are cochairmen of the Committee on Research of the National Food and Beverage Council.

The extent of the problem can be seen, Senn and Logan said, by the production of frozen pies which in 2 years has accelerated ten times to 250 million units in 1954. Another

factor is the increase in number of restaurants which have factories for the production of take-out foods which are becoming ever more popular with the industrial worker.

Although local health departments devote much time to restaurant and food processing sanitation, there is need for a similar amount of time and effort to be given to the supervision of "take-out" foods operations, Senn and Logan said.

Other points of their discussion of the problem included the following:

The frozen food industry must recognize certain dangers and be on guard against them. Among these are: various paratyphoid organisms in eviscerated poultry; paratyphoid and typhoid bacilli surviving for long periods of time in frozen foods; the botulism organism and its toxin which remain potent after prolonged freezing.

In some plants, as many as 25 pairs of hands work over take-out chicken pies, as the ingredients move along the assembly line.

Field inspections showed that the poultry and other raw ingredients were of reasonably good grade, but there were no official, routine inspections at some plants.

High standards can be reached. One study with cold and hot packed samples showed that the product packed hot was practically sterile, they said, while the cold products averaged 4,000 to 6,000 organisms per gram on bacteria plate counts.

Proper packaging, clear labeling, and public education can help solve the consumer's problems. No matter how sanitary the product is, it can become spoiled if kept too long at room temperature.

The Los Angeles area has improved sanitation factors in the industrial catering business. New regulations permit handling hot foods on a trial basis, provided hot foods not sold on the first day are discarded.

Rules for the installation and operation of rotisseries afford reasonable control up to the time the food is sold.

Water Pollution Control . . .

Topics included in this section are tests to detect water pollution and to trace infectious agents, the plentiful use of water as a shigellosis preventive, the Southwest's water supply shortage, and sewage management.

Plentiful Water Supply May Reduce Shigellosis

Lack of water for personal hygiene and laundry may be a significant factor in the prevalence of *Shigella* infections, according to the findings of 1952-53 studies among residents of migratory farm labor camps in Fresno County, Calif.

The study was reported by A. C. Hollister, Jr., M.D., M. D. Beck, M.A., A. M. Gittelsohn, M.P.H., and E. C. Hemphill, M.P.H. They said there were no other environmental factors to explain the association between availability of water and the number of *Shigella* infections found in these camps.

Dr. Hollister is chief and Mr. Beck and Mr. Gittelsohn are with the bureau of acute communicable diseases, California State Department of Public Health. Mr. Hemphill is with the Epidemiology

Branch, Communicable Disease Center, Public Health Service.

Hollister and his co-workers reported that in the 70 camps studied during a 7-month period, the proportion of persons with positive *Shigella* cultures varied inversely with the availability of water. In camps in which all cabins had either private or inside water faucets, 0.7 percent of the cultures from individuals were positive. However, in camps in which none of the cabins had inside water faucets, the rate was 7.2 percent positive.

The investigators said that the rate of prevalence of *Shigella* infections ranged from 1.6 percent in cabins with complete inside plumbing to 5.8 percent in cabins which had no inside plumbing. Among the cabins which had inside water faucets only, with other facilities outside and available for communal use, 3.0 percent of the cultures were positive, they said.

Shigella positivity rates, by water availability.

Results of a study of the relationship between prevalence rates of *Shigella* infections and the amount of water available for personal hygiene in southern Georgia confirm the findings of the Fresno County investigators, Hollister and his co-workers stated.

Environmental Control

The findings of the California and Georgia studies indicate that when water is used for washing and bathing, it can aid in the reduction of intestinal infections, acting as a diluent instead of as a vehicle for the transmission of pathogenic organisms, they continued. The implication is that the relatively inexpensive provision of plentiful and easily accessible supplies of water will bring about significant improvements in the control of *Shigella* infections.

Hollister and his co-workers said that these studies are the first organized efforts "to isolate some of the elements of environmental sanitation and personal hygiene practice and to begin to evaluate them in order of preventive importance for a particular disease entity," and that "only by defining such fundamentals can programs for improving the health status of depressed populations anywhere be brought to maximum efficiency."

In conclusion, they said that this hypothesis must be subjected to critical tests in the field, possibly in several situations in various parts of the world, and suggested that it might be desirable to include other diseases than shigellosis in these tests.

Trace Infectious Agents By Sewage Sampling

Results of three projects illustrate the suitability of the swab technique for sampling sewage and, in combination with appropriate isolation methods, for isolating infectious agents which may occur intermit-

tently in sewage, according to Sally M. Kelly, Ph.D., Mary E. Clark, and Marion B. Coleman, division of laboratories and research, New York State Department of Health.

The swab technique, as suggested by British workers, offers a practical approach to the problem of searching for *Salmonella* carriers among groups of food handlers, they declared. The ease and safety with which the swabs may be handled cannot be ignored, they added.

Salmonella Typhosa

After the occurrence of a third case of typhoid fever in the vicinity of a stream into which the effluent of a town's sewage treatment plant was discharged, they related, a search for the carrier of typhoid bacilli, phage type D₄, was instituted.

Strips of gauze, 6 by 48 inches, were folded to make swabs and sterilized, then immersed in sewage at points which covered a specific street, they reported. After 4 days' immersion the swabs were removed and each swab was placed in glycerol solution and received at the laboratory within 24 hours, they said.

Salmonella typhosa was isolated from 10 of 29 specimens, including one from the sewage drainpipe of a nursing home, but not above this point in the sewerage system. The carrier was discovered in the nursing home, they reported.

Coxsackie Viruses

A study of the distribution of Coxsackie viruses in sewage, using the catch and swab sampling methods, showed that the swabs yielded viruses more consistently than the samples taken by the catch method, they reported, and that:

Coxsackie viruses are found in sewage from June through November, the peak occurring in late July and early September. The viruses were recovered in 7 of 9 sewage plants examined "in season." During December through May, the viruses are found only sporadically, if at all. The viruses are not destroyed by sewage treatment, in par-

ticular, by Imhoff tank sedimentation and certain phases of secondary treatment. The viruses occur intermittently during the daily flow, and more than one serologic type may be present in a sample.

Tubercle Bacilli

Specimens from the sewage of two treatment plants which serve large tuberculosis hospitals were examined to determine the effect on tubercle bacilli of primary and also secondary treatment, consisting of trickling filter clarification followed by chlorination, they stated. The findings show a decrease in the number of tubercle bacilli by both methods of sewage treatment, they reported, but neither method is entirely effective.

Tests Favor Enterococci As Pollution Signals

Reconsideration of the use of the enterococcus group of bacteria as indicators of sewage polluted water is advocated by Warren Litsky, Ph.D., and W. L. Mallmann, Ph.D., as a result of a 2-year study of Connecticut River samples.

Dr. Litsky, associate research professor, University of Massachusetts, and Dr. Mallmann, professor at Michigan State College, found an enterococcus density approximately 7.6 times that of *Escherichia coli*, the organism commonly used to indicate water pollution. In a statistical analysis of the bacteria determinations, they demonstrated a definite relationship between the two types of organisms. The increase in the *E. coli* index, they said, was generally followed by a predictable increase in the enterococcus index.

During the 2-year period, water samples were collected at least twice monthly from 14 stations in areas of both low and high pollution along the Connecticut River in the vicinity of Northampton, Mass. The 7.6 to 1 ratio of enterococci to *E. coli*, the highest reported ratio thus far, is

based on the median value of all samples collected in the study.

This finding, Litsky and Mallmann said, "suggests that the enterococcus organisms be taken out of the realm of stepchildren and given their legitimate place in the field of sanitary bacteriology as indicators of sewage pollution." They pointed out that enterococci have been found to be abundant in fecal matter, but, unlike the coliform bacteria, they have not been found anywhere in nature.

Superior Medium

They attributed their results to the use of a superior medium for detecting and enumerating enterococcus organisms. Azide dextrose broth (Difco) was used as a presumptive test for the enterococci and ethyl violet azide broth as a confirmatory medium.

The low numbers of enterococci recovered from sewage and polluted water in several previous investigations, they believe, was due to the failure of the media employed for their isolation and not to the low numbers of the organisms. Cited as an example was the 63 to 1 ratio of *E. coli* to enterococci reported by Lattanzi and Mood in a 1951 study of water samples taken from the harbor at New Haven, Conn. The Winter and Sandholzer technique was used on the harbor water samples.

Leading to a review of the coliform-enterococcus ratio in sewage polluted water, they related, was the earlier demonstration by Mallmann and Seligmann that azide dextrose broth was far superior to other media for the detection of streptococci in water and sewage. Using this medium, Mallmann and Litsky recovered about the same number of coliform bacteria and enterococci (intestinal streptococci) from soil freshly treated with sewage.

Because the azide dextrose broth supported the growth of a few other nonstreptococcal forms, Litsky, Mallmann, and Fifield developed ethyl violet azide broth as a confirmatory medium. The presumptive and confirmatory media, it was re-

ported, detected 100 to 10,000 more enterococci in polluted water than were detected by other methods.

Litsky and Mallmann concluded that more work must be done along this line if the isolation and detection of enterococci is to become a method useful in sanitary bacteriology.

Limited Use Credited To Ultraviolet Purifier

In the event of an emergency involving failure of municipal supplies, naturally contaminated water can be made safe for human consumption by the use of an individual ultraviolet purifier.

Such an apparatus was described and results of the first systematic study on factors influencing the ability of ultraviolet radiation to kill bacteria were presented in a report made by the following: H. C. Ricks, M.D., M.P.H., director of laboratories, T. D. Labecki, M.D., medical consultant, F. J. Underwood, executive secretary, and G. R. Reeves, senior bacteriologist, Mississippi State Board of Health, Jackson, Miss.; and J. R. Cortelyou, Ph.D., chairman, department of biological sciences, M. A. McWhinnie, M.D., associate professor of biology, and J. E. Semrad, Ph.D., professor of biology, DePaul University, Chicago.

The purifier is particularly useful in areas where it is difficult to solve problems of water supply by sanitation and engineering measures. With an adapter and a standard automobile electrical system, it can also be used to purify water during camping, hunting, and fishing trips, and in areas where drinking water is unsafe.

Radiation Intensity

Although the purifier has certain definite limitations, these are clearly stated and are provided for in the apparatus. The report said that even heavily contaminated water can

be safely purified by this means, provided that adequate intensity of radiation is established and maintained. This will depend on several factors: number of hours the lamp used has been burned; maintenance of proper line voltage and water temperature; effect of mineral and organic content of the water on transmission of radiation; differences in the resistance of various bacterial species to ultraviolet radiation; duration of exposure of all particles of water to the germicidal energy of the ultraviolet rays; and observance of certain precautions by operators of the apparatus.

Results of laboratory and field tests refute statements that various circumstances may make it impractical to purify water by ultraviolet radiation, Ricks and his associates reported. Apparently proper design of the purifier will compensate for these limiting factors.

They warned, however, that purification of contaminated water on an individual consumer basis should not be allowed to replace sound public health measures for the provision of safe public water supplies and that the purifier should not be considered a replacement for efforts to improve individual sources of water.

Urges Sanitation Studies In Hepatitis Research

The actual number of cases of infectious hepatitis resulting from waterborne virus is undoubtedly much greater than the number reported, according to C. H. Connell, Ph.D., professor of sanitation, department of preventive medicine and public health, University of Texas School of Medicine, Galveston.

More precise recognition of the disease and better reporting of cases is one of the prerequisites for adequate epidemiological studies of this disease, he asserted. A second prerequisite, he said, is the development of methods for titrating the virus other than by use of human volunteers.

The epidemiologist should take the lead and, with other members of the health team, obtain a better evaluation of environmental factors important in transmitting the disease, he declared.

Needed Research

In the field of water and sewage purification, Connell asserted, the following research investigations are needed:

Measurement for effectiveness in removing and inactivating hepatitis virus under conditions approximating those of plant-scale operation of water treatment processes, coagulation, sedimentation, filtration, and chlorination; evaluation of the effect of pH upon those processes; and a more precise evaluation of the effects of chlorine, particularly when free chlorine alone is present; a similar comprehensive study of the effectiveness of sewage treatment processes; and an evaluation of bacteriological coliform test as an index of fecal contamination in relation to the presence or absence of hepatitis virus in water.

Septic Tank Failures Cause Concern

Outlining the tentative recommendations of the APHA Committee on Rural Sanitation, its chairman, John E. Kiker, M.C.E., professor of civil engineering, University of Florida, asserted, "Septic tanks and subsurface sewage disposal systems are poor substitutes for central collection systems and treatment facilities."

There is no substitute for the application of basic engineering principles in the proper design of subsurface sewage disposal systems, he added. As a result of many failures, which may be attributed to a disregard of these principles, septic tanks have fallen into disrepute in recent years.

Most of the septic tank failures have occurred in suburban areas

where public sewerage facilities should have been required, he noted. Unfortunately, Kiker commented, few health departments have the authority to require such facilities where they are needed, and it is doubtful whether the number of sewerage systems will ever be enough to supply the needs.

The nuisances caused by overflowing sewage at private dwellings are found mainly at project subdivisions and could be prevented by proper planning and enforcement of regulations, he stated.

As two-thirds of the houses being built are in suburbs not served by public sewers, the Nation faces the problem of making the best of a bad situation for years to come, he said. Sewage overflows will probably continue to be the most common public health nuisance, but it will be possible to minimize such nuisances through the exercise of judgment and adherence to basic engineering principles, he commented.

Use of Septic Tanks

In general, Kiker said, septic tanks should be used only in rural areas of large acreage where suitable soil for disposal of the effluent is available. The tanks should not be used where the soil is impervious, where the ground water table comes within 4 feet of the surface during the wettest season, where the subsoil is otherwise unsatisfactory, or where there is any likelihood of contaminating a body of water.

All subsurface disposal systems, he continued, should be designed on the basis of percolation tests made in the soil after thorough saturation. In the case of shallow devices for sewage disposal, the soil characteristics for a depth of at least 5 or 10 feet should be determined. Underground characteristics and percolation tests should be correlated in estimating the probable life of a subsurface disposal system, he said.

Kiker outlined preliminary considerations in designing septic tanks and subsurface sewage disposal systems: percolation tests, estimates of

sewage quantities, area and distance requirements. He also cited 18 standards which have been successful in some places.

The reporting committee was composed of A. N. Best, Robert N. Clark, William T. Ingram, Robert W. Lambertson, Louva G. Lenert, Harvey F. Ludwig, Joseph A. Salvato, Jr., James R. Simpson, and Samuel R. Weibel.

Southwest's Water Supply Problems Are Increasing

By the year 2,000, nearly three times as much water will be needed in the Arkansas-White-Red River Basins as is needed today. These potential water supply requirements, especially for industry and municipal use, will present a problem to all public health agencies, particularly State health departments, stated E. C. Warkentin, B.S., M.P.H., E. P. Sellner, M.S., and H. W. Poston, B.S.

Mr. Warkentin is officer in charge and Mr. Poston is assistant basin engineer, Lower Mississippi and Western Gulf Drainage Basins Office, Public Health Service, Little Rock, Ark.; Mr. Sellner is the Public Health Service representative on the Domestic and Industrial Water Supply Group.

Surface and Ground Waters

Surface water problems vary in the three river basins, Warkentin and his colleagues said. In the western half of the area, rainfall is low most of the year, and at times, water may be unsatisfactory or even unusable. In the eastern half, most of the streams have a continuous flow, but during dry periods, the smallest streams cannot be depended upon unless the water is impounded.

Natural salinity and disposal of industrial wastes and municipal sewage affect the chemical quality of the water, and storage reservoirs in the Arkansas and Red River Basins must have a large capacity to allow for the accumulation of sediment.

The quality, quantity, availability,

and suitability for domestic and industrial uses of ground water vary with the character and productivity of the ground water provinces traversed by the major rivers in the basins, Warkentin and his co-workers said.

Oil brine has damaged ground water in some areas; in others, natural pollutants have resulted in poor quality of water. In rural communities, water in more than half the wells is unsafe for human consumption, and in some areas, no water is available and supplies must be hauled in.

Warkentin and his colleagues recommended further investigation of the feasibility of replenishing ground water supplies in areas where they have been depleted by intensive irrigation of rice.

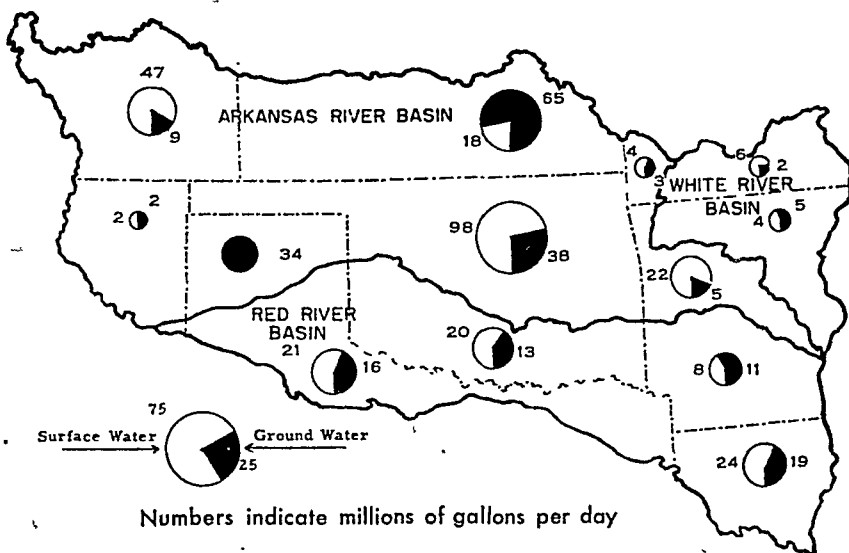

Possible Solutions

Some industries and municipalities can increase existing sources of water supply; several multiple-purpose reservoirs in the basins have storage capacity or maintain a low flow of water for pollution abatement and water supply; 11 reservoirs have been authorized or are recommended for Federal construction; and legislative authority has been given to modify some reservoirs, provided certain conditions are met by States, municipalities, and local agencies, Warkentin and his co-workers reported.

They said that 40 reservoir projects with a total storage capacity of more than a million acre-feet, which could be used by 75 or more communities, are apparently economically feasible in this area, that hydroelectric storage power would amount to 1,726,000 acre-feet, and that water releases from power production could be used for water supply purposes.

They also stated that water from a sparsely settled area in the Red River Basin which has an abundant supply of excellent quality water from the combined flow of four rivers may eventually be pumped as far as 150 miles from its source.

Municipal water use from ground and surface sources in the Arkansas-White-Red River Basins, by State sections of drainage basins.

Warkentin and his colleagues said that the States in the Arkansas, White, and Red River Basins and the Arkansas-White-Red River Inter-Agency Committee have been studying the problems of water resources

and supplies in this area since 1950. The committee's report and plan for the development of water and land resources in these river basins is to be presented to the Congress on June 30, 1955.

School Health Practices . . .

Rochester, N. Y., finds no special case-finding value in the school medical examination of first grade children who had been examined a year before, and Stanford University finds no special benefit in separate classes for the child who has had rheumatic fever. Minnesota University's unusual health service has been designated a local health unit.

New York Studies Role Of School Medical Exams

A study in Rochester, New York, has found that a school medical examination of first grade children who have been examined in kindergarten is valueless from a case-finding standpoint, according to a report by Alfred Yankauer, M.D.,

M.P.H., and Ruth A. Lawrence, M.D.

Dr. Yankauer is director, bureau of maternal and child health, New York State Department of Health, and Dr. Lawrence is pediatrician, Rochester Health Bureau, and instructor, University of Rochester School of Medicine and Dentistry.

Of 997 previously examined children, 210 had adverse conditions,

they specified, but 164 of these were already under medical care and 25 were already known by the school health service to have the adverse condition.

Of the remaining 21 children, only 1 had a serious condition which had developed since the previous examination and which could not have been observed by a classroom teacher, they noted. This child had epileptic seizures which occurred only at night. Two other children of the 21 had Baker's cyst of the knee.

These data were obtained, Yankauer and Lawrence explained, from the first of four examinations that have been or will be made each year on the same children. In addition, each year after the first, a control group of children at the same grade level but in other schools will be examined. The prevalence data from the first examination serve primarily to provide a baseline for analysis of future findings, they pointed out.

To define more accurately the role of periodic medical examinations in the school health program and to clarify the role of the school physician were given as objectives of this 4-year study. It will explore some of the following questions, Yankauer and Lawrence said:

Are the traditional purposes of a periodic medical examination (to detect adverse conditions, to advise concerning the need for care, and to educate parent and child) realistic today? How necessary is periodic examination of the entire school population for detecting adverse conditions? How frequently should medical examinations be performed to achieve their stated purposes? What is the annual increment of adverse conditions detectable only by medical examination? How many conditions detected by the medical school examination are already under care?

Study Methods

Medical examinations performed for this study consisted of a com-

plete and careful medical history and a physical examination of all systems, they specified. Included in the report, however, were data only on conditions the detection of which requires the skill of a physician. Tests for visual acuity and hearing loss and other laboratory screening tests, such as urinalysis and tuberculin tests, were not performed.

The study group for the first examination was composed of 1,056 first grade children (including 59 not previously examined), 97 percent of the 1952-53 first grade population of 13 schools in Rochester, N. Y., they stated. From each of three socioeconomic groups of schools, four or more were selected so that the first grade population in each group would represent a 15-percent sample of the total first grade population of that group.

No Advantages Shown in Health Class Study

The post-rheumatic fever child benefits no more from special health classes than from regular classes, Raymond George Nebelung, Dr.P.H., Ed.D., department of public health and preventive medicine, Stanford University School of Medicine, maintained in describing a 2-year study made of 444 such children in San Francisco.

To determine the value of special education over regular school routine, the study grouped the children in two sections: (1) health classes with a curtailed school and activity program; and (2) regular classes with the normal type of school activities.

Features of the special health classes included special teacher training in education of the handicapped child, small classes, modified teaching program, shorter school day, scheduled rest periods, and a supplementary nutrition program. In the regular classes no restrictions were put on the post-rheumatic child's activities, Nebelung said.

Cardiac classification categories were set up for the two types of classes, using for each child the original and current classification data from the cardiac registry of the San Francisco Board of Health. No case was selected for the study until at least 1 year had elapsed following the child's illness. The physician's physical finding on examination of each child determined the child's classification.

The data for the two groups were compiled in terms of retrogression, no change, or improvement in the child's condition. Analyses of the data showed no significant differences in degree of improvement existing between the members of the health classes and the regular classes for the various years studied, Nebelung stated.

However, supervision of the physical activities of the post-rheumatic fever child is essential, Nebelung stressed. The child must be taught to recognize his own capacities and to conserve his energy while the damaged heart muscle is repairing. The question becomes one of types and amount of exercise in which the child should be encouraged to participate. But, at present, no specific technique is available to measure accurately the functional capacity of the heart.

Nebelung urged both physical educators and physicians to strive for improved techniques for classifying post-rheumatic heart cases.

Air Disinfection Reduces Bacteria, Not Illness

Even children who live in isolated rural areas and spend most of their day at school experience sufficient extracurricular contacts with bacteria and viruses to outweigh any benefit from a substantial bacterial count reduction in the air of their schoolrooms and school buses, according to the results of a 9-year air disinfection study of 4 schools in upstate New York.

The report, fourth in a series, is a résumé of bacteriological investi-

gation since 1945, two members of the New York State Department of Health reported. They are F. Wellington Gilcreas, assistant director in charge of laboratories for sanitary and analytical chemistry, and Hazel R. Read, division of laboratories and research.

Comparative studies of treated rooms and untreated control areas, they said, show that both ultraviolet light and triethylene glycol vapor reduce the number of bacteria in schoolrooms, but that the reduction has no significant effect on viruses and the incidence of measles, mumps, chickenpox, or on respiratory illness. The same results were obtained when triethylene glycol treatment was applied to school buses where 60 to 100 percent of the children were in close daily contact. No significant change in the day-to-day absentee rates resulted, they reported.

Contrast Shown

Gilcreas and Read said that irradiation of rooms by ultraviolet lamps resulted in decreases of 37 percent in the total bacteria per cubic foot, 39 percent in bacteria settling per square foot per minute, and 44 percent in streptococci.

Glycol vapor, said Gilcreas and Read, was carried through the rooms with air circulated by school ventilating systems. This method achieved reductions of 60 percent in the total bacteria per cubic foot, 55 percent in the bacteria settling per square foot per minute, and only 11 percent in streptococci.

Under the conditions of their study, glycol vapor appeared to produce high reduction in the number of miscellaneous bacteria but was not as effective against streptococci as ultraviolet light.

They concluded that the hours away from school and the chance for contact transmittal of viruses and bacteria in the total environmental situation play such an important role that neither ultraviolet light nor glycol vapor can effectively reduce illness.

Add Sanitation Services At Minnesota University

The environmental sanitation program of the University of Minnesota student health service functions just like a sanitation division in a local health department. This unusual student health service has been designated a local health unit by the Minnesota State Board of Health, according to Richard G. Bond, M.S., M.P.H., associate professor of the university's school of public health.

The majority of college health programs do not assume responsibility for standards of sanitation, Bond pointed out. Such programs are frequently concerned only with food services, student dwellings, garbage disposal, and the like.

Continuing his analogy, Bond, who as public health engineer heads the university's sanitation staff, said:

Minnesota's nearly 30,000 students, 3 campuses, 8,000-acre research center, 2 villages of temporary housing, airport, and other facilities make the university comparable to an average community, but with accentuated problems. These reasons and the university's academic and research activities give unusual scope to the environmental health program.

Close cooperation is maintained with other programs of the student health service and with all operating units of the university. For example, arrangements have been made so that waste lines carrying potentially hazardous wastes are tagged and plumbers are instructed not to initiate repairs without first contacting the health service.

The program expanded after World War II, when a sanitary code was adopted. The program includes the usual activities of water supply sanitation, waste disposal, plumbing, housing, food and milk sanitation, insect and rodent control, plus some very specialized areas, namely—radiological safety, industrial hygiene, and general safety. To show why these safety programs have been added, Bond cited facts:

More than 20 different university departments actively engaged in radioisotope research make area and personnel monitoring and environmental control a necessity.

The university employs a labor force of approximately 4,500 and more than 3,000 faculty members. In addition to the student body, these persons are all exposed to industrial hazards, many of which are magnified in the laboratories.

Nineteen percent of the injuries reported take place in the students' residences. Many of these can be prevented by a safety program attacking the hazards to which the students are exposed.

Other factors which increase the variety of the program, he noted, are the presence of a large medical center, the necessity for special pre-employment medical examinations and annual rechecks for all food service workers, the inclusion of programs of preventive medicine, and even the problem of stream pollution.

Nurse Home Visits Boost Corrective Action Rate

New procedures in the followup of school health examinations increased by one-third the percentage of children taken to a physician for corrective action, announced William G. Mather, Ph.D., Lauris B. Whitman, Ph.D., A'Delbert P. Samson, Ph.D., and Mary E. Ayers.

Dr. Mather is professor of rural sociology, Pennsylvania State University; Dr. Whitman is director of field research, National Council of Churches; Dr. Samson is assistant professor of rural sociology, Montana State College; and Miss Ayers is a research associate, Pennsylvania Department of Health.

In 15 Pennsylvania schools using the new procedures, they reported, the corrective action rate for medical defects was 60.7 percent, whereas in 5 schools not using the procedures, the rate was 45.6 percent.

A new record card that shows at a glance the progress made and the work done by the school nurse toward securing corrective action was the basic tool in the experiment, Mather and his associates specified. By means of colored tabs across the top edge, the card shows whether or not a defect (medical or dental) exists, the number of times the school nurse has contacted the family, and whether or not the contact has resulted in corrective action.

Effects of the new procedures were determined through interviews with families of the children, they noted. Interviewing was done by public health nurses 75 to 90 days after the school health examinations. It covered 97 percent of 484 children having medical defects and 96 percent of 1,117 having dental defects.

The corrective action rate for dental defects, they said, was apparently not influenced by the new procedures. They reported rates of 59 and 60 percent, respectively, for the experimental and control schools, from which fact they concluded that the problem of dental corrective action is very different from that of medical corrective action.

Other Significant Findings

Concerning the value of school health examinations, the study revealed the following:

1. For 46 percent of the children with medical defects and for 68 percent of the children with dental defects, the parents already knew of the defects before the school examination.

2. Of every 10 children given a medical examination, only 0.7 of a child whose parents had not known of the defect before the examination was taken to a physician.

3. Of every 10 children given a dental examination, 1.2 children whose parents had not known of the defect before the examination was taken to a dentist.

Mather and his associates tentatively concluded that the present return from routine school health examinations is not satisfactory for the

time and money spent and that the examination itself should be made more of a learning experience for both pupil and parent. They pointed out, however, that although the schools were carefully selected, they would not claim the study results to be typical of conditions in Pennsylvania.

Socioeconomic Factors

Also investigated was the relation of specific socioeconomic factors to taking corrective action for medical

and dental defects. On the basis of the data obtained, they stated:

" . . . the chances of a child's receiving corrective action . . . are best if the parents know about the defects before the examination, if the father has a college education, if the residence of the family is urban . . . if the income of the family is \$4,000 or more a year, if the parents are relatively active . . . in school affairs . . . and if the family consists of only 1 or 2 children below the age of 18 years."

Mental Health Studies . . .

Data from cohort studies on first admissions to a mental hospital are interpreted and show areas of needed mental health research. The emotional tensions for which classroom teachers and situations are responsible are discussed. A plea is made for school health workers and classroom teachers to work together as an example of good mental practice to their students. Evidence is presented that one-third of the adult population is responsible for a major part of illness among adults.

Finds One-third of Group Have Most Illnesses

Supporting evidence for the thesis that a small proportion of the adult population is responsible for a large part of all the illness among adults was presented by Lawrence E. Hinkle, Jr., M.D., and Norman Plummer, M.D., both assistant professors of clinical medicine at Cornell University Medical College.

They also found in the "ill" group a general susceptibility to all types of illness and accidents in contrast to the well-known phenomenon of specific susceptibility to certain forms of illness.

Their conclusions are based on the study of two homogeneous groups of industrial workers—1,237 women and 1,527 men—in a metropolitan

telephone company. The women were telephone operators and the men skilled craftsmen.

In addition to sex, occupation, and place of work, the members of each group were similar in age, cultural background, socioeconomic status, area of domicile, physical condition when first observed, nutrition, and environmental safety, sanitation, and general opportunity for exposure to infection. Each member of the groups had been continuously observed during his period of employment, some for more than 35 years, they reported.

The Ill One-third

Hinkle and Plummer found that about one-third of each group accounted for more than three-fourths of the episodes of illness and four-fifths of the days of disability at-

tributable to the entire group. This finding, they said, confirms the results of other sickness studies of industrial groups.

Frequent minor illnesses, interspersed with major episodes, was the consistent sickness pattern for the "ill" one-third in each group, they said. This third, they reported, also had a disproportionate number of accidents, both major and minor.

They found that the many minor illnesses were scattered throughout many organ systems. The major illnesses were also in several organ systems, usually in those showing the most frequent minor disturbances.

The individuals who had the greatest number of bodily illnesses and accidents also had the greatest number of disorders of feeling state, thought, and behavior, they reported.

By contrast, they said, another one-third of each group had less than 5 percent either of illness episodes or days of disability. Members of this "well" group had a few scattered minor illnesses in several organ systems, and major illnesses after a long period of well-being were the exception rather than the rule.

The Stress Factor

Pointing out that the data lend no support to the concept that one inferior organ system was the main cause of the ill health of the frequently sick persons, Hinkle and Plummer suggested that the persons in the "ill" group were exhibiting a disturbance of function of the whole organism and that each illness represented an isolated manifestation of a total and continuing pattern of reaction.

Good or poor health, they stated, was most clearly correlated with the individual's relation to his psychosocial environment in adult life. All of the ill men and women studied medically, they found, had difficulty in meeting the demands of their special life situation, and all of the well people had adaptive capacities uniquely suited to their life situation.

They observed that a number of the "ill" persons who had been healthy in childhood and had grown up in a benign environment began to develop illnesses when they were inadvertently precipitated into stress producing life situations that were not of their own making.

These observations suggest, according to Hinkle and Plummer, efforts directed at the study of the host may be as rewarding as past studies directed at disease syndromes.

Mental Health Is Called Keystone of Education

Mental health is that quality which makes the acquirement and use of education possible, declared Dana L. Farnsworth, M.D., professor of hygiene, Harvard University, in a discussion centering around the opportunities for the school health worker or physician to promote mental health.

If it is assumed that education includes intellectual, emotional, social, and spiritual components and that it is the forerunner of wisdom, mental health is a keystone in the structure of education, Farnsworth stated. He defined mental health as "that state of mind in which one is not only free to go about the business of living but actually does so with zest and satisfaction."

Mental health in the schools, he declared, should be thought of in terms of the central purpose for which schools exist, that is, to enable pupils to make optimum use of the qualities, actual and potential, they possess. Accordingly, mental health is a matter of morale, of honesty, of concern with prejudice, discrimination, cheating, fanaticism, hatred, and how teachers and pupils think of one another.

Farnsworth suggested that instead of looking for formulas for the proper rearing or education of children, one might more profitably think in terms of attitudes and inner qualities. The really important matters, he said, are

habits of thoughtfulness, of thinking how it must appear to the other person, of awareness of the sensitivity of others, and of a general respect for people.

Training in feeling is fully as essential for the truly educated person as training of the intellect, he maintained, listing the following items which should be considered in the education process: the capacity to give and receive affection, the ability to show anger and to tolerate it in others, the recognition of the presence of strong instinctive reactions such as pride, jealousy, and fear.

The School Health Worker

Mental health is everyone's business, Farnsworth said, but the school health worker and the teacher play especially important parts in the building of mental health, since they see and work with the child while fundamental attitudes toward life are still capable of betterment. They can also work with parents in a constructive direction, he added.

The important qualities needed by the school health worker and the teacher are an awareness of the need for and scope of mental health and the will to do something about it, he remarked.

It is the duty and the opportunity of the school health worker, he continued, to collect and assimilate knowledge gained from the study and treatment of the disturbed and unhappy youngster and to transmit that knowledge in the form of general principles to the classroom teacher. The teacher, on the other hand, sends to the health specialists a constant stream of information about his views of the school's educative process.

This process of working together and learning from one another helps to promote mental health in the school because it enables pupils to see good mental health in action, he explained. He pointed out that students learn infinitely more from what they observe in their teacher's behavior than from what they are told.

Mental Hospital Studies— Pinpoint Research Need

Areas for needed basic research in mental illness have been sharply delineated as a result of the studies by the Warren State Hospital, Warren, Pa., and the National Institute of Mental Health, Public Health Service. For example, what happens to the discharged mental hospital patient is virtually an unexplored field.

Reporting for the hospital were Superintendent Robert H. Israel, M.D., and Nelson A. Johnson, M.S.W., director of social service. The Public Health Service was represented by two members of the institute: Morton Kramer, D.Sc., chief, Biometrics Branch, and Hyman Goldstein, Ph.D., chief, Current Reports Section, Biometrics Branch.

Their joint report concentrated on the trend in probabilities of separation from the Warren State Hospital—either alive or dead within specified time periods following first admission—for patients of specific age, sex, and diagnosis. Admissions to the hospital were analyzed on a cohort basis according to traditional life table methods.

The Cohort Studies

Persons admitted to a hospital for the first time, suffering from functional and syphilitic psychoses, now have increased chances of being returned to the community and decreased chances of dying in the hospital, the authors reported.

"Such facts are quite important in getting community acceptance of the mental hospital as an active, dynamic, medical facility, and in doing away with the idea that once a patient is committed he is lost to his family and to society forever," they pointed out. Among other purposes, the cohort studies were planned to provide historical data against which current mental hospital practices can be evaluated.

Warren State Hospital has abstracted data on first admissions since 1913. Because it offered a more

Percentage of first admissions retained in Warren State Hospital (Warren, Pa.), released alive, and dead within specified periods following admission, 1916-50.

All mental disorders, all ages, both sexes.

All mental disorders, under 65 years, both sexes.

All mental disorders, 65 years and over, both sexes.

complete picture of admissions than did other mental hospitals, it was chosen for study. The periods 1916-25, 1926-35, 1936-45, and 1946-50 were compared because they coincided with events in the history of the hospital that might have had major significance in the treatment of patients. Findings were based on a study of the rates of release alive and of death in the hospital for a total of 15,472 men and women.

The Chances of Release

Some of the facts developed by the studies and the questions they lead to are:

Of patients admitted in the period 1916-50, more were released alive within 1 year following admission than were released alive within 5 years of the patients admitted in the period 1916-25. In none of the periods studied was the proportion of patients released within 5 years after admission less than 50 percent, a much higher proportion than was expected.

The youngest patients, 15-34 years, have extremely high probabilities of release alive. Patients 75 and over have a very small chance of ever leaving the hospital alive.

Between 1916 and 1950, the first admission rate increased in all age groups, and particularly for the age group 65 and over. It increased 126 percent for the age group 75 and over.

Does this mean a true increase in the incidence of mental disorder in the northwestern Pennsylvania area served by Warren State, or is it merely an increased use of expanding facilities?

The probability of release in the first year following admission for patients with functional psychoses in the period 1916-50 was considerably in excess of what it was for patients admitted in each of the earlier periods.

Does this mean that the various therapies used in increasing volume—electroconvulsive therapy, insulin, group psychotherapy, and occupational therapy—have been responsible for this increase in re-

lease rates, or have other factors been responsible?

Patients with senile and cerebral arteriosclerotic psychoses have very small probabilities of being returned to the community alive. Their death rates, particularly in the first few weeks and months following admission, are exceedingly high.

What are the social, economic, and familial factors responsible for bringing a very high proportion of moribund patients into the hospital?

Functional psychotics, as well as other categories of patients not released in the first year of hospitalization, experience considerably reduced probabilities of release in the second and subsequent years of hospitalization. Also, patients admitted during 1916-50, who have attained their second and third years of hospital life, have approximately the same chances of being released in the following year as had similar groups of patients in the earlier cohorts of admission.

What are the etiological and other factors responsible for long-term hospitalization? What treatment methods can be developed to make it possible to return more of these individuals to the community? What can be done to improve the lot of the patient who cannot be returned to society?

Teacher Can Aid Child To Grow in Own Way

*"Let me grow as I be,
And try to understand why I want
to grow like me;
Not like my Mom wants me to be,
Nor like my Dad hopes I'll be,
Or my teacher thinks I should be,
Please try to understand and help
me to grow
Just like me."*

This bit of verse, Helen T. Watson, R.N., said, expresses the kind of classroom freedom which has tremendous implication for schools and the mental health of children. Children need teachers who enjoy teach-

ing—and believe in the ability of children and adults to learn, develop, change, and grow, each in his own way. They need teachers who understand teaching, she said.

Watson, a consultant for school health services, Connecticut State Department of Education, emphasized the need for an atmosphere in the classroom which stimulates the child to grow and develop in accordance with his own capabilities and without the fear of unfavorable comparisons with his classmates.

For Those Who Teach

Children need teachers who find ways of enriching their own personal lives, who are adequately prepared and willing to continue to study that they may more fully understand children who appreciate parents and seek opportunities for working with them, Watson stressed.

The personality of the understanding teacher calls for a healthy attitude toward differences in culture, racial and ethnic patterns of behavior, and the influence of social and economic status on behavior. Teachers and other school personnel must become familiar with differences in values and purposes of children in a multigroup society, she continued.

Children need educators who promote the kind of "atmosphere which permits flexibility whether it be in planning the curriculum, deciding on disciplinary measures, or establishing personnel policies," she said. This permissiveness can be successful only where there is relaxed, easy, interpersonal relationships between teacher and school administrator, teacher and teacher, teacher and pupil, and teacher and parent.

Classroom Tensions

Educational leaders have made it clear that teachers who are unaware of what the lives of the children in their classrooms are like may unintentionally create and foster feelings of inadequacy and tension, Watson stated.

One educational practice that has stimulated such reaction is a system of grading scholastic achievement which is based on comparing the educational progress of one child with that of others in his class. Too often a child can construe this as failure and subsequently interpret it as punishment.

Indiscriminate isolation, as a punishment, may serve the teacher, she said, but not the child who interprets it as a point for being docile and submissive in order to be successful, Watson stated. Equally strong in their lasting influence on the child are the "constant nagging pressures" which stem from frequent experiences of hostility communicated by teachers and parents or from the failure of adults to accept normal childlike behavior.

"It should be recognized that

growth takes place slowly and that it may take the guidance and encouragement of several teachers through several years and grades to produce behavior changes in a child," Watson continued.

Not to be discarded are some very basic principles, which, when applied, can make positive contributions to the mental health of children. As examples of these precepts for teachers, she listed and discussed the following: All behavior is caused; the human personality grows in the direction of the best adjustment of which it is capable; the ability to face reality even though unpleasant must be encouraged; people face difficult situations with fight or by flight; it is neither necessary nor desirable to be too serious about teaching and guiding children.

science of radiological health. There should be no hesitation in asking such staff members to prepare themselves to understand and apply radiological health principles, he declared.

Requisites for Success

On the basis of the New Jersey State Health Department's experience in developing a radiological health program, Bergsma said the following are essential for the success of such a program:

1. Training for field and office personnel.
2. Supportive legislation, in order to define the scope of authority to recommend radiological health controls wherever necessary.
3. Preparation of a concise declaration outlining proposed activities.
4. Ability to impart authoritative radiological health information and specialized advice to all interested parties.

Remaining Task

Thinking in terms of public health administration, public health practice, and public health education, Bergsma said a tremendous task remains to be done. He listed the following objectives for the establishment of standards:

1. Administrative standards: To define in detail the extent to which public health administration of radiological health controls is desirable and feasible.
2. Educational standards: To suggest methods and provide information concerning inservice training in radiological health for public health and allied professional health personnel.
3. Regulatory standards: To establish methods of contacts and provide information for self-regulation by qualified groups or professions.

In Bergsma's opinion, a new governmental control agency is not needed to deal with the problems of radiation exposure. He believes the problems can be met by presently employed personnel. It may be, he remarked, that many of the problems cannot now be resolved by public

Radiological Health . . .

Problems of occupational and coincident radiation exposure can be dealt with cooperatively by health, legal, and industrial personnel. Training veterinary inspection personnel to evaluate radiation problems in food and food animals will reduce economic and dietary loss from food wastage.

New Jersey Anticipates New Nuclear Industry

New Jersey's fundamental approach to the problem of radiation exposure is occupational, specified Daniel Bergsma, M.D., M.P.H., commissioner of health, New Jersey State Department of Health.

Extension of the program to provide for protection of the general public, however, has followed naturally and necessarily, he said. The use of sources of ionizing radiation is essentially occupational, but the coincident exposures of the general public must also be considered, he maintained.

Citing the Atomic Energy Act of 1954 and the words of President Eisenhower concerning it, Bergsma predicted the appearance of new producers of nuclear energy within a relatively short time. This act opens the door, for the first time, for development of a private atomic power industry. He urged State and local health agencies to prepare, as soon as is feasible, to answer the many questions that will result from expansion of the nuclear industry.

It has been demonstrated, he pointed out, that public health engineers, industrial hygienists, and public health physicians and nurses are able to adapt themselves to the new

health personnel alone, but they will be solved by reference to other health, legal, and industrial problems with the assistance and support of respective experts in these fields.

Radiation Effect on Food Concerns Veterinarian

Radioactive contamination of the environment is a potential threat to man not only directly but also through its effects on the animal population, Maj. U. S. Grant Kuhn III, VC, USAF, indicated in remarks on radiation hazards to the Nation's food supply.

Major Kuhn is veterinary officer, Atomic Energy Commission, Oak Ridge, Tenn.

Concerning ways in which animals might be exposed to radioactive elements, Kuhn said that fallout, or

radioactive dust, from a nuclear detonation may settle on herbage which is consumed by domestic animals, or this fallout may enter the food supply through the soil.

Pointing out that food wastage resulting from hysteria and misinformation is just as serious an economic and dietary loss as that resulting from unwholesomeness, he reported that a training program for veterinary officers of the Army and Air Force has been inaugurated to prepare them to evaluate radiation problems concerning food and food animals.

It is hoped, he said, that by training reserve officers and veterinary inspection personnel engaged in other public health organizational activities information may be eventually disseminated throughout that portion of the veterinary profession upon which the public depends for certification of a wholesome food supply.

ized region, he related. The approach is not rigid and methods will be improved through experience, he commented.

Routine measurements on a continuous basis provide information on dustfall, airborne particulate matter, and sulfur dioxide. Continuous records have also been obtained of visibility, extent of solar illumination, soiling index of the air by fine aerosols, and meteorological variables already mentioned, he reported.

Through environmental sampling techniques, areas of high and low pollution were selected and sampling stations were established in 28 census tracts in Detroit, he reported. The same procedure was followed in Windsor and 25 sampling stations were set up. On the basis of observations by these sampling stations, areas highly polluted and areas with low pollution, containing well-defined population groups and matched socioeconomically as far as possible, were selected for morbidity study, he reported.

The initial objective was to obtain information on the incidence of symptoms and illness among those in the various study areas, Katz related. This health study was started late in the summer of 1953, and the health records for the first year are now being assessed by a group of experts, he said.

Control of Air Contaminants . . .

A nationwide air sampling and evaluation study, measurement and reduction of odor, evaluation of bacterial air samplers, and toxic pollutants are among the air pollution subjects covered in this section.

Study Prolonged Exposure To Air Contaminants

Despite great advances made in the last 5 years, much remains to be studied toward elucidating the causes of acute symptoms leading to fatalities in air pollution disasters, according to Morris Katz, Ph.D., chairman, Canadian section, Technical Advisory Board on Air Pollution, Defense Research Chemical Laboratory, Ottawa, Canada.

Necessary for a sound approach to the problem of chronic injury are data of fundamental environmental

and meteorological observations on a continuous basis concurrently with measurements of ill health in properly established pollution and control areas, he asserted. Meteorological investigations needed include measurements of wind speed and direction, lapse rate and turbulence, temperature, humidity, precipitation, visibility, and solar illumination.

The Detroit Study

The Detroit-Windsor study is aimed at determining the effects of prolonged exposure to atmospheric contaminants of a highly industrial-

Chronic Effects

The atmosphere of industrial communities contains a great number and variety of organic and inorganic contaminants, he said. Complicating the situation are reactions of a photochemical and catalytic nature which occur between gases and vapors or between gases and particulate matter after liberation in the air, he asserted.

The inorganic fraction of the complex matter suspended in air includes a considerable number of metallic elements. The most abundant are silicon, calcium, aluminum, iron, magnesium, lead, and manganese.

Small amounts of zinc, copper, titanium, tin, vanadium, cadmium, and beryllium are also present. These elements represent about 10 to 20 percent of the total weight of the airborne particulates, he pointed out. A number of industrialized cities in the United States and the Windsor-Detroit area show only minor variations in the percentage composition, Katz said.

The composition of the organic contaminants is still largely unknown. It is probable that the organic fraction in air pollution is of greater importance in the study of chronic effects on health, Katz stated, than the inorganic material under normal circumstances in an industrial area. When the level of contaminants increases under adverse weather conditions, the concentration of the organic portion of airborne particulates tends to increase much more than the inorganic fraction.

Causes and Symptoms

In the Donora case, U. S. Public Health Service studies concluded that no single polluting agent was present in sufficient quantity to account for the acute injury to the population's health, he said. Responsibility was placed on a synergistic factor involving some combination of contaminants.

The general and special physiological effects of the Donora and Meuse valley incidents are similar, he declared. The symptoms and signs were irritation of the eyes and respiratory tract followed by coughing, nausea, vomiting, headache, and dyspnea, he reported, and added that there were also varying stages of circulatory collapse, cardiac decompensation, and pulmonary edema.

Death was due predominantly to acute cardiac failure with or without obvious pathology, Katz said. The elderly, those with respiratory diseases, cardiovascular diseases, or asthmatics were the majority of victims.

Tells How to Evaluate Bacterial Air Samplers

In recognition of the need for uniformity in the evaluation of bacterial air samplers, William Lester, Jr., M.D., Chicago University associate professor of medicine, presented an outline of tentative methods for determining their efficiency. He remarked that no foolproof technique exists. Only by the laborious checking of each variable can valid results be obtained, he said.

Essential to Lester's outline is the understanding of the meanings of collection efficiency and retention efficiency, which he explained. Both efficiencies, he said, should be determined for each sampler studied. He outlined the following procedures as necessary to the detailed evaluation of the physical and biological performance of a specific sampler. Once the procedures have been found valid, he added, a short cut becomes evident.

Suggested Outline

1. In order to obtain reproducibility and uniformity of particle size distribution as a basic prerequisite for any comparative analysis of sampler performance, it is necessary to control these parameters: temperature, relative humidity, conditions of atomization, chemical constituents used in the culture media and atomizing vehicle, rates of flow and sampling, position and site of sampling, and also the metabolic and functional status of the biological agents used.

2. It is difficult to obtain satisfactory control of all these factors in a static chamber because of the interference of various local variables; therefore, to obviate these difficulties, a dynamic chamber should be used in conjunction with a nonreflux type of constant delivery atomizer, in which the aerosol is generated and evacuated at a uniform rate.

3. Collection and retention efficiencies should be determined upon a quantitative basis using an inert, nonvolatile, stable aerosol. They

should be determined for the various rates of flow and over different ranges of particle size so that the specific physical efficiencies of the sampler can be fully characterized.

4. Whatever tracer technique used, whether the aerosol contains water or oil soluble dyes, specific chemical tracers, or radioactive agents, it is important that the technique be capable of accurate quantitative measurement in low concentrations and that the substances used are uniformly distributed throughout all the particles contained in the aerosol.

5. The determinations of efficiency should be made upon both wet and dry aerosols of various (suggested) particle size ranges, from the largest size capable of aerial dispersion down to the minimum diameter of particles capable of containing a bacterial cell.

6. Studies should be made of the collection and retention efficiencies of a specific air sampler for biological aerosols made up of viable bacterial cells because many factors present in atomization and sampling can influence the survival of bacterial cells.

7. The basic comparative evaluation of bacterial air samplers must be made upon aerosols containing only micro-organisms of species normally dispersed into the air by human beings. All cultures should be carefully standardized as to their state of growth.

8. The evaluation studies with bacterial aerosols should follow the same general procedure advised for the determination of physical collection and retention efficiencies but using bacterial counts instead of colorimetric or gravimetric determinations.

9. Because of the profound influence of relative humidity upon the size characteristics and survival of bacterial aerosols, it is worth while to correlate the efficiency and performance of any given sampler with various (suggested) relative humidities.

10. The same ranges of particle size distribution advised for the inert

clouds should be studied for use with the bacterial aerosols.

Engineers Measure Odor, Now Reduce Its Effect

An industrial plant's air pollution control program using \$2.8 million worth of equipment and requiring \$700,000 annually to operate was described by Virgil E. Gex, in charge of pollution control engineering, Procter and Gamble Company, Cincinnati, Ohio.

The cost breakdown, he reported, shows that \$1.4 million was spent on cyclones and filters for process exhausts. The \$250,000 annual operation cost, he said, is believed to be exceeded by the value of the material recovered.

Cyclones and filters for room dust control systems cost \$400,000 to install and \$80,000 per year to operate, he said, and added that recovery from such systems is not believed to pay its operating expenses. One million dollars has been spent on equipment to reduce, eliminate, or dispel odors, Gex reported. The operating costs for this equipment runs over \$400,000 per year, he commented, and there is no product recovery.

Odor Research

Work on odor control began 9 years ago, he said. The first problem was a lack of any quantitative concept of odor. The conventional approach had several weaknesses and a method of measuring odor directly was developed.

He defined an odor unit as the amount of odor necessary to contaminate 1 cubic foot of air to the odor threshold—a level barely detectable by the sense of smell.

Osmo

To find an odor unit, a sampling device, nicknamed the "Osmo," was developed. It uses a continuous flow of 10-20 c.f.m. of odor-free reference air into which increasing amounts

of odorous sample is introduced until odor is found in the exit mixture, Gex explained. This gives a ratio upon which to base measurements in odor units per cubic foot, he added.

Once emission rates for various discharges in order units per minute can be calculated and compared on a common basis, Gex declared, odor reduction efforts can be more easily concentrated on big discharges first.

Odor emission rates can also be used to calculate how high a stack should be to keep the maximum ground concentration below one odor unit per cubic foot, he pointed out.

Osmo has made it possible to use lower and more efficient temperatures in several furnaces used to deodorize process exhausts, he added, and thus to save \$50,000 annually, on fuel bills.

Odor Control

Four methods employed and examples of their application to control odor pollution, Gex related, include stack dispersal and:

Operating techniques. Reduction of odor discharge by changed operating technique involves little investment. Conventionally, cleaning tank cars involved liberal steaming. The excess steam, escaping from the tank car carried a good deal of rancid fat odors. A satisfactory steaming procedure was worked out, eliminating the odor nuisance.

Process change. One batch operation process discharged odors during one part of the batch cycle. Although more expensive, the processing was converted to a continuous operation to reduce the total odor discharge. Also, changing from line steam to recirculation jet in the acidulation of soap stocks reduced odor discharge to $\frac{1}{500}$ of its former value.

Control equipment. A variety of equipment is used including spray condensers, enclosed vent systems, packed scrubbers, Venturi scrubbers, odor furnaces, activated carbon filters, centrifugal separators, and air filters.

Nonspecific Irritants in Air Implicated in Smog Studies

Citing "unquestionable evidence that air pollution can contribute to health impairment," Norton Nelson, Ph.D., of the Post-Graduate Medical School, New York University-Bellevue Medical Center, concluded that nonspecific irritants acting additively may be one of the most important toxic effects of air pollutants for the respiratory system. Dr. Nelson is professor of industrial medicine and director of the school's Institute of Industrial Medicine.

On the basis of available data concerning effects of respiratory irritants, Nelson advocated further study of the following points:

1. The probability that a person already under stress may suffer significantly from a level of an irritant innocuous to a healthy person, and, similarly, the possibility of enhanced susceptibility of the very young and the very old.

2. The possibility that the physical state of pollutants influences their effects on the respiratory system.

3. The possibility that irritants other than those conventionally accepted as important may contribute to the problem.

Donora and London

The difficulties observed during the Donora, Pa., smog of 1948 and the London fog of 1952 seem to be attributable to the fact that a non-specific respiratory irritant or group of irritants impose an additional stress on an already overburdened respiratory or cardiac system, Nelson specified.

Investigation of the Donora incident has shown, Nelson said, that a real and systematic increase in "complaints" occurred and that they occurred with greater frequency where preexisting disorders were present.

Nelson noted also that there was unquestionably an association between the increase in the concentration of sulfur dioxide in the atmos-

Schematic presentation of the mechanism suggested by Haagen-Smit to explain the observed effects of smog in Los Angeles.

phere and the increase in deaths during the London fog. Nelson felt, however, that other irritants may have been important.

Functional Changes

That air contaminants may produce functional changes, as contrasted with organic changes, has been suggested by studies on the effects of inhaling sulfur dioxide and sulfuric acid mists, Nelson stated. Amdur and associates showed that reflex changes in pulse rate, tidal volume, and respiration rate occur with the inhalation of these substances at levels well below the detection threshold.

Since the functional operation of an organ may be distorted or modified by a toxin without leaving any evidence of trauma if the insult is survived, Nelson advocated a search for such functional changes in relation to air pollutants.

Another significant point demonstrated by these and other studies is that sulfur in the form of sulfuric acid appears to be as much as five times as toxic as sulfur in the form of sulfur dioxide, Nelson stated. This may arise from the fact that sulfuric acid is a stronger acid, but Nelson considered equally or even more important the fact that sulfuric acid exists in the form of particles, whereas sulfur dioxide exists in the form of a gas.

Evidence suggests that the depth of penetration in the lungs of water-

soluble gases may be increased when they exist in the form of very small particles, he said, theorizing that, if this be so, irritants borne by small particles may reach a more susceptible tissue and therefore produce increased toxicity.

Lung Cancer and Air Pollution

Nelson considered the available data bearing on a relationship between general air pollutants and lung cancer inadequate as a basis for any definite conclusions. He summarized the present knowledge of this subject as follows:

1. There is probably a higher incidence of lung cancer in urban than in rural groups.
2. Urban and industrial centers have higher concentrations of known carcinogens than areas with less air pollution.

Discuss Increased Accent On Air Pollution Studies

Airborne effluvia resulting from man's own activities have emerged lately as nuisances, causes of severe economic loss, contributors to discomfort, and occasionally, as killers, Leslie A. Chambers, Ph.D., Vernon G. MacKenzie, B.S., and Milton J. Foter, Ph.D., reported.

Dr. Chambers and Dr. Foter are with the Robert A. Taft Sanitary

Engineering Center, and Mr. MacKenzie is with the Division of Sanitary Engineering Services, Public Health Service.

Air pollution is a problem of such magnitude that no one locality, no national center, can be expected to make significant progress without coordination and collaboration with other groups, they stated.

Irritating and damaging smogs, such as the one at Donora, Pa., have made clear that smoke abatement is only a facet of the problem, Chambers and his associates said. Recent technical literature stresses the complexities of air sampling, the identification and control of specific pollutants, the chemical reactions in the air, and the economic and health effects of airborne substances.

Air pollution episodes less severe than that in London in 1952 occur in many places. A mechanism for correlation of vital statistics with pollution variables is necessary, Chambers and his associates said.

Prior to 1954 the Sanitary Engineering Center initiated three exploratory projects: (1) the nationwide sampling program seeking knowledge of the amounts of particulate material in the air over a group of arbitrarily selected cities; (2) an attempt at statistical correlation between available mortality data from a large metropolitan area and measured meteorological and pollution data covering the same period of years; and (3) a continuing effort in assembling information concerning local evaluation, investigation, and control of air pollution and its problems.

Now five types of activities are being started:

1. Expansion of the exploratory sampling network, including more problem areas as well as intensification of study in areas already activated.
2. Immediate initiation of work on the evaluation, and where necessary, the development of sampling equipment and analytical procedures for gases and volatile substances.
3. Study of physiological effects

of air pollutants so that control standards can be established.

4. Extension of the exploratory attempt at correlation between pollution loadings and mortality data to include several other cities.

5. Initiation of a technical study of community control patterns related to the air pollution problem.

The objectives of the last study, Chambers and his co-workers said, will include the determination of necessary survey patterns; procedures for obtaining unified support for programs in regions involving more than one governmental unit; probable legislative requirements and other guideline data.

said, they are indirect and partial indicators of the basically intangible characteristic of patient care.

Clinical Judgment

Clinical evaluations, while less precise, may be more valid since they offer a more direct approach, she said. In this type of appraisal, she explained, qualified consultants appraise hospital records in the various clinical fields, such as medical, surgical, obstetrical, nursing, and social service, and score the performance according to prepared standards.

There are, she said, widely accepted concepts of what is meant by good care, and thus the reliability of qualitative judgment can be tested and subjected to statistical analysis. Sheps stressed the need to obtain the appraisals of several independent judges. "Only through separate evaluations is it possible to assess the consistency of the individual judgments and to arrive at a relatively unbiased estimate," she said.

Sheps pointed out that although any of the four approaches to the quality of hospital care involves comparisons, either indirectly through the use of standards or directly, the basis of comparison is vital in program evaluation.

If a specific procedure has an effect on quality, it must be revealed in differences, she said, adding that to find such differences, the hospital under study must be compared with something—either with other hospitals or with its own earlier performance.

Lack of Data Complicates Hospital Care Comparison

Because diseases are the same throughout the country, every hospital patient should have the same good care, no matter where he resides nor what hospital he enters, said Paul A. Lembecke, M.D., associate professor of public health administration, Johns Hopkins Uni-

Hospitals, Home Care . . .

Measurement of quality of hospital care, reimbursement problems of regional hospitals, and the advisability of a hospital-operated home care program for special disease conditions are discussed in this section.

Approaches to Measuring Hospital Care Quality

Methods of measuring the quality of hospital care were discussed by Mindel C. Sheps, M.D., M.P.H., research associate of the department of biostatistics, Harvard University School of Public Health.

Most of the work done to date has been related to setting minimum or desirable standards for accreditation and in stimulating improvements in hospital care, Sheps stated. The field of program evaluation is just beginning to be explored, she said.

Main Approaches

Sheps described four of the main appraisal techniques that can be used alone or in combination: (1) examination of prerequisites for adequate care, such as minimum or optimum levels of facilities, equipment, professional training, or organization; (2) performance elements, such as autopsy and cesarean rates, or accuracy of diagnostic procedures; (3) results obtained on patients, such as

postoperative, puerperal, and neonatal mortality rates, or incidence of postoperative infections; (4) qualitative clinical judgment.

Any of the appraisal indexes and standards used should be clearly defined, based on comparable data, and examined for reliability and validity, Sheps said, adding that statistical controls and analyses should be applied to the clinical appraisals as well.

As one of many examples illustrating the need for study of appraisal indexes and the difficulty of setting valid standards, Sheps cited the use of postoperative death rates as an index to effective care: "Does the death rate within 10 days after major chest surgery really reflect the quality of care? What about the effect of such patient characteristics as diagnosis, complicating illnesses, age, sex, and nutritional status?"

The first three techniques were termed objective indexes that hold considerable promise for the appraisal of hospital care. However, she pointed out, they are not yet the ideal measuring tools. At best, she

versity School of Hygiene and Public Health.

If a hospital is not equipped with staff and facilities to provide care of good quality for certain diseases or conditions, that hospital should refer such cases to hospitals that are better equipped, Lembcke maintained.

Regional organization of hospitals, he believes, is one important method by which the integration of needs and resources can be accomplished.

Preferring to avoid using different standards for different hospitals, Lembcke recommends the publication of more actual data as essential to measuring the quality of hospital care. He pointed out that conclusions based on studies made in one hospital alone, not related to all hospitals in the community, tended to be erroneous or actually misleading because the patients are a select group and not representative of the general population.

He said data such as those published by the Saskatchewan Hospital Services Plan, the Windsor Medical Services, and the Health Insurance Plan of Greater New York had proved helpful in measuring his own studies in Rochester, Indianapolis, Petersburg, Cooperstown, and other areas.

Lembcke cited the need for figures on excessive surgery and on the incidence of certain diseases as an approach to the use of quantitative methods of measurement. "I know," he said, "this is often a very ticklish subject, studies being made chiefly in hospitals where it is suspected that the quality is not what it should be." But the identity of the hospitals studied need not be made known, he countered.

Boston Home Care Study Tests Selectivity Benefit

A home care program will be more effective if it serves all types of illness rather than limited disease categories. This conclusion was drawn from the results of a 2-year trial

Comparison of services for study group and control group in Boston City Hospital home care program

Service	Study group (55)	Control group (35)
Physicians' home visits.....	1,515	-----
Home visits per patient.....	27.5	-----
Outpatient department visits.....	80	231
Visiting nurse association visits.....	1,030	393
Visits per patient.....	18.7	11.2
Percent of patients visited.....	58.2	31.4
Frequency of visits (weekly).....	2-3	1-2
Hospitalization:		
Total days.....	857	434
Number of admissions.....	50	39
Admission rate per 1,000 patients.....	909	1,115
Cardiac hospitalization:		
Total days.....	203	239
Number of admissions.....	10	27
Admission rate per 1,000 patients.....	182	772
Noncardiac hospitalization:		
Total days.....	654	215
Number of admissions.....	40	12
Admission rate per 1,000 patients.....	727	343

home care program for selected Boston City Hospital cardiac patients.

Reporting the study were Henry J. Bakst, M.D., professor, and Edward F. Marra, M.D., instructor, department of preventive medicine, Boston University School of Medicine.

Under the conditions of the study, 55 persons in the study group and 35 persons in the control group were selected at random from hospital ward cardiac patients. Both groups were discharged home without care by a private physician. The patients were comparable in severity of illness and economic and social status.

Patients in the study group received individual medical care on a 24-hour-a-day, 7-day-week call basis in their homes or, if necessary, in the outpatient department; visiting nursing care; and social services by the hospital medical social worker and community agencies.

Home examinations included electrocardiograms, venipunctures, and thoracenteses. Medical services included dressing of varicose and post-phlebotic ulcers, applications of Unna's paste boot, and, in one instance, placement of improvised drainage tubes.

The control group received medical care in the outpatient department or through emergency home visits that were usually followed by rehospitalization.

Range of Illness

The intensive home care reduced the rate of hospitalization for heart disease, they reported, but it increased materially the hospitalization rate for noncardiac disease. Thus, they said, the total rate of hospitalization in both groups for all causes was essentially comparable.

Readmission to the hospital because of exacerbation of cardiac symptoms occurred more than four times as frequently in the control than in the study group, they explained, but hospital readmission for noncardiac diseases was more than twice as frequent in the study group (see table).

Since the hospitalization costs were about the same for both groups, the home care service for the study group was an additional cost item, they reported. However, they pointed out, the home care service permitted better and more effective med-

ical service and thus isolation of the costs is difficult if not unrealistic.

The amount of associated disease found in the study group indicates that comprehensive medical care programs actually increase the variety of services needed by aged or chronically ill groups, Bakst and Marra observed. The Boston experience, they said, emphasizes the contribution an effectively organized and developed home care program can make through case finding, early diagnosis, and treatment of incipient illness.

Attempts to develop programs for a single disease category are probably unjustified except to form a base for broader and more inclusive services, they concluded.

Children's Hospitals Face Reimbursement Problems

Under present conditions, the regional hospital assuming responsibilities for the rehabilitation of various childhood disabilities is operating at financial disadvantages, according to Lendon Snedeker, M.D., M.P.H., and Edward S. Lancaster.

Dr. Snedeker is assistant administrator, Children's Medical Center, Boston, and Mr. Lancaster is its comptroller.

Burn cases cost the hospital \$31.86 a day, but it is reimbursed \$27.02, they said. These patients require an average 105 days of bed care. Daily cost for congenital heart disease patients varied from \$31.73 to \$50.50, but the reimbursable cost is \$26.99, and the ward charge, \$17.00. On these youngsters, the hospital loses an average \$50-\$100, or more. In cases of cleft palate and harelip, the cost situation is more favorable to the hospital.

Reconstructive surgery in such situations has been undertaken with the implicit understanding that the charge per day or per case will considerably exceed the standard reimbursable cost figure, but it is doubtful that the two will ever balance out. Even though it operates

at a financial loss, the hospital must live up to its obligations in the fields of service, teaching, and research.

The administrators suggested that regional problems be financed on a regional basis in order to eliminate the dispensing of charity from local funds. One-third to one-half of the rehabilitation cases admitted to Children's Medical Center come from outside the Boston area, yet it, like other large children's hospitals, is the logical reference point for the difficult rehabilitative cases. Repeated spot checks have shown that these children are referred for a wide variety of conditions, most of which cannot be effectively diagnosed or treated in their own communities.

More figures are needed as to the rehabilitation costs for various types of childhood disability, both from the standpoint of the funding agency and of the hospital providing the service, Snedeker and Lancaster said. With this in mind, the medical center has begun to maintain a register of children admitted for such care. Also needed is a thorough case study for the total cost of finding, diagnosing, and adequately treating any particular childhood handicap, they pointed out. Such study ought to ascertain family outlay for private medical care and travel as well as the expenses incurred by the family or any medical agency for special operations, after-care, and training.

Nutrition in Institutions . . .

Food planning in institutions, cooperation between State and local health agencies in providing nutrition services, standards for hospital diets, and food practices in nursing homes are the subjects of this series of papers.

Ohio Nutrition Service Aids Local Institutions

Cooperation between State and local agencies can help meet the responsibility for providing nutrition services for institutions, according to Ralph E. Dwork, M.D., M.P.H., acting director of the Ohio Department of Health.

Institutions such as general, tuberculosis, or mental hospitals, children's or nursing homes, and homes for the aged frequently need help with their nutrition problems, Dwork said, pointing out that local health departments cannot always meet this need. State consultation services, he believes, should be made available in many areas of service—in preplanning kitchen layout, in

teaching best use of equipment, in menu planning, in food purchasing, in preparation and serving of food, in control of wastes, and in control of costs. The Ohio State Health Department provides these services when the local units cannot or do not provide them, he stated.

The availability of trained personnel has not kept pace with the stepped-up hospital building program in Ohio, Dwork reported. He said that Ohio has directed its building efforts toward the smaller cities and rural areas, its areas of greatest need. This expanding program, still short of the recommended goal of 4.5 beds per 1,000 patients, creates a greater need for dietary personnel.

In Ohio today, 90 general hospitals, 14 tuberculosis hospitals, 19

mental hospitals, 140 children's homes, and over 600 nursing homes and homes for the aged have inadequately trained dietary personnel, Dwork reported. Hospitals in the larger cities, with higher salaries, shorter working hours, and offering better professional associations appear to be more attractive to the trained, Dwork asserted.

Dwork said that inservice training of untrained dietary workers under direction of a trained dietitian is a possible solution to the shortage problem in some cases. Another way out, he said, is joint hiring of a qualified dietitian by several institutions.

Exploring New Areas

The principle of offering service to local health departments and not directly to local communities guides the policy of the Ohio State Health Department, Dwork pointed out, but Ohio entered the field of dietary consultation direct to institutions on the basis that a State health department should explore new areas, whether or not called upon by the local departments to do so. The State, he said, will relinquish this function when the local health departments take over the task. In the meantime, local health departments are helping jointly with training, demonstration, and instruction of individuals or groups of patients, Dwork reported. Food sanitation services, Dwork said, are a local responsibility wherever and whenever possible. When not possible, he implied, it becomes the State's affair.

Indiana Aids Hospitals in Food Planning

Indiana has been among the first of the States to recognize the importance of nutrition in institutional care, Margaret A. Dunham, M.S., chief nutritionist of the Indiana State Board of Health, reported.

In January 1948 the State board of health employed an institution nu-

trition consultant to help the 129 general and allied special hospitals, 74 children's institutions and day nurseries, and the 33 county homes for welfare recipients with their dietary and food service problems, Dunham said.

More recently, in July 1943, she reported, the 17 mental and correctional institutions were included in the improved food program when a dietary consultant was added to the staff of the board's newly formed mental health commission.

During the past 6 years, Dunham said, the institution nutrition consultant's work has covered four major areas: surveys to check compliance with the nutrition standards required for annual State licenses; consultant services to individual hospitals; consultation on dietary facilities in new or remodeled hospitals; and group instruction.

The initial survey of the then 124 hospitals revealed that in 63 hospitals, food service was supervised by untrained persons, Dunham reported. Only 52 employed a trained dietitian, and in 9 a home economics graduate was in charge of the dietary staff. Since 56 of these hospitals had 50 beds or less, they obviously could not afford a trained dietitian and needed the consultant's help, she said.

The consultant reported a general lack of understanding by the hospital personnel about the makeup of a nutritious diet, Dunham said. Many hospitals needed help in planning general and modified menus and in improving food service to patients and personnel, food preparation and storage methods, dishwashing procedures, arrangement of kitchen equipment, and economical food purchase, she said.

Surveys of the children's homes revealed that many of them were planning meals more suitable for adults, Dunham said. Meals are often inadequate in quantity for teen-agers. They lacked variety, and combinations were unattractive; suppers often consisted of leftovers from the previous meal.

During the past year, Dunham reported, 26 hospitals requested assistance from the nutrition consultant. In addition to a monthly evaluation of their menus, she has made 4 or 5 visits to the hospitals.

Dunham told of the consultant's work in a 27-bed tuberculosis hospital—a typical example of her assistance.

On her first visit to the hospital in 1949, Dunham said, the consultant found the menus were low in green and leafy vegetables; eggs were served only twice a week, and suppers consisted of food served cold plate style. Menus were planned on a day-to-day basis.

The consultant, she said, has been instrumental in bringing about the following improvements: menus that will more nearly meet the nutritional requirements of tuberculous patients; purchase of milk in individual containers for the patients; installation of new dishwashing equipment; replacement of a wornout, two-compartment sink; and better food-purchasing methods.

Dietary conferences have been held for hospital personnel since 1951, Dunham reported, and a series of 1-day institutes have been organized for matrons, board members, and cooks in the children's homes.

PHS Studies Standards For Hospital Diets

Nutrition standards provide hospitals with a yardstick with which to measure adequacy of foods, stated James M. Hundley, M.D., chief, Laboratory of Biochemistry and Nutrition, National Institutes of Health, Public Health Service, Bethesda, Md.

They also serve as a baseline for the management and control of food and for the preparation and review of budgetary requests, he continued, and they are particularly useful when a number of hospitals are supervised from a central point.

Hundley suggested, however, that, because of the variation of nutrition-

al needs in different types of institutions, standards should be sufficiently flexible to account for local circumstances. Probably no single nutrition standard can be applicable and valid for all hospitals, he said.

Today's nutrition standards might better be called nutritional goals, Hundley said. The standards recommended are the result of studies made in 1952 and 1953 in five completely different types of Public Health Service hospitals—general medical and surgical, neuropsychiatric, tuberculosis, leprosy, and research.

Modifications of the dietary allowances recommended by the Food and Nutrition Board of the National Research Council for healthy, physically active persons were used as the basis for the nutrition standards in all of the hospitals in the study, Hundley said. The hospital diets were noticeably higher in protein, vitamins, and minerals than the diets recommended by the Food and Nutrition Board.

Hospital Standards

Patients in the general hospitals are usually males who are accustomed to a physically active life and to a relatively high food intake, Hundley said. A large proportion are ambulatory during their entire hospital stay and an appreciable number are nutritionally depleted when admitted. Some modification in favor of protein and vitamin C content was made in these hospitals to account for trauma, surgery, and other hospital factors.

Mental patients frequently eat little or develop bizarre food habits, and it is important that the food served them be high in quality and in nutrient content, Hundley stated. He said that the majority of the patients in neuropsychiatric hospitals are ambulatory, and that many of them work about the hospital station doing heavy farm labor, dairy-ing, and other physical work.

In both the tuberculosis and leprosy hospitals, diets are high in calories, protein, minerals, and vita-

mins, including vitamin D. Most of the patients in these hospitals are undernourished on admission, and many of them are bedridden for long periods and cannot get out into the sunshine.

The standards for the research hospital—Public Health Service Clinical Center—were set up before the hospital was put into operation, and were based on an average of the nutrition standard set up for general hospitals in this study and on similar standards set up by the Food and Nutrition Board for physically active women, Hundley stated.

Standards Practical

Reports on nutrition in 4 general, 1 tuberculosis, and 1 leprosy hospital indicate that the nutrition standards are practical and that food costs are reasonable, Hundley said. In the 4 general hospitals, standards were met or exceeded as follows: calories, 2 hospitals; protein, vitamin A, riboflavin, and ascorbic acid, all 4; calcium, 2; thiamine, 1; niacin, 1, and iron, 3.

Diets in the tuberculosis and leprosy hospitals met or exceeded the nutrition standard, Hundley said, except that the tuberculosis hospital failed by a very slight margin to meet the calcium standard.

Nursing Home Nutrition Theory Versus Practice

If the diets for patients in nursing homes are to be adequate in amount and in the essential nutrients, and if the food practices in these homes are to meet good standards, more information is needed on how actual food and nutrition practices compare with good theoretical standards.

Joseph H. Kinneman, M.D., deputy commissioner of health, and Ruth Nelson, R.N., public health consultant for institutions, Nassau County Department of Health, John H. Browe, M.D., director, and Elizabeth Agnew, nutritionist, bureau of

nutrition, New York State Department of Health, reported the findings of a cooperative study of 20 licensed nursing homes in Nassau County, N. Y. The study, made in the summer of 1954, agreed completely with the cumulative records maintained by the local health department since 1941.

All homes had a sufficient supply of canned goods to last a week, and 65 percent had adequate supplies for a month; supplies of perishable foods were sufficient in most to last a week.

In most instances, food storage was better than in public eating and drinking places. No dietitian or a person with training in nutrition was employed in any home, and in most places, the cook was given little or no supervision or direction.

The quantity, preparation, and service of food were good. The heartiest meal was served in the middle of the day. Dining rooms or dining areas were seldom used, even when available; tray service was the rule. Regular diets did not always include the "basic 7." Vegetables and fruits, particularly a daily serving of green or yellow vegetables and citrus fruit, were not the rule, but all homes made some provision for special diets.

Water supplies, sewage disposal facilities, dishwashing practices, and food handling techniques were good in all, and these practices were better than those found in commercial eating establishments. The frequency of garbage collection was satisfactory, but garbage storage was not.

Suggestions and Recommendations

Kinneman and his co-workers made these suggestions for changes and improvements in food and nutrition practices:

More use of garnishes to make food attractive in appearance.

A later supper hour—in only 15 percent of homes was there a 10-hour interval between breakfast and supper.

More careful supervision of the cook, and development of menus and standardized recipes subject to approval by a person qualified in the field of nutrition.

Expansion of kitchen space, replacement of old equipment, and addition of mechanical aids to food preparation and to food and utensil care.

Improvement of the physical setup of dining areas and the encour-

agement of more use of dining room facilities.

More attention to the modification of special diets, according to changes in the clinical condition of the patient.

Finally, Kinneman and his colleagues suggested that a study be made of a comparable group of nursing homes, which have been subject only to accreditation by a State agency, for comparison with the findings of the Nassau County study.

is rapidly lost on dilution of serum and passed through embryonated eggs. Death of eggs in 2-6 days was the endpoint.

Experiments were conducted with 26 persons exposed to NDV and 26 controls. Serums from 21 of the 26 exposed individuals neutralized more than 10 ID₅₀ doses of NDV as did one serum from the control group, due to a cross reaction with mumps antibody. High neutralizing activity, inhibiting over 10,000 ID₅₀, was present in the serums of 11 exposed subjects who had a history of conjunctivitis.

Despite frequent and intense exposure by the respiratory route, there was no history of frequent or severe infections of an influenzal nature, he reported.

Tentative Hypothesis

Evans opinion is that NDV is only capable of producing conjunctivitis in man. The possibility of mild respiratory illness cannot, however, be entirely excluded, he commented, but depends on the emergence of variants with greater human pathogenicity. The ability of some mumps immune serums to inhibit NDV may indicate more than one mumps strain, one of which shares antigens in common with some NDV strains.

As the interaction of certain infectious mononucleosis serum and NDV is mediated only through red cells altered by NDV, this may represent a chance uncovering of a new antigen on the red cell surface by NDV which makes them agglutinable by such serum, he suggested.

New Antityphoid Agent Shows Promise

A single injection of purified Vi and O antigens, the components of *Salmonella typhosa* considered important in immunization against typhoid infection, evokes the production of higher levels of antibody than a complete course of three injections of the conventional killed bacilli vac-

Immunology . . .

The avirulent rickettsial strain vaccine used experimentally against epidemic typhus and the live virus vaccine used in the Georgia rabies epidemic in dogs are favorably reported. A properly conducted neutralization test is preferred for the immunological diagnosis of Newcastle disease virus, and a new antityphoid agent offers promise.

Newcastle Disease Virus Neutralization Test

In immunological diagnosis of Newcastle disease virus (NDV), a properly conducted neutralization test is the technique of choice in the opinion of Alfred S. Evans, M.D., of the departments of preventive medicine and medical microbiology, University of Wisconsin School of Medicine.

Diagnosis, whenever possible, should rest on isolation of NDV in a laboratory free from possible accidental contamination, he asserted.

An immunological diagnosis should be made carefully and only after nonspecific inhibitors have been eliminated, and the serum has been shown to contain no mumps antibody, he said.

Primarily an acute infectious disease of fowl, Newcastle disease is of importance as a possible human

pathogen because of its striking resemblance to the mumps-influenza virus group, he commented. NDV has been established as a cause of acute conjunctivitis in humans, but the relation of the virus to acute hemolytic anemia is not certain.

Laboratory work on analysis of NDV by hemagglutination, complement fixation, and neutralization tests has resulted in confusing and misleading data, he asserted, and it has been difficult to establish the presence of NDV antibody in human serum.

Recommended Test

Evans outlined the procedure for the recommended neutralization test as follows:

Serums were heated at 56° C. for 30 minutes to destroy nonspecific heat-labile component. Undiluted serum was mixed with varying dilutions of virus, since antibody effect

cine, reported Maurice Landy, Ph.D., chief, department of bacterial immunology, Army Medical Service Graduate School.

On a weight basis, only 10 percent as much of the purified antigens are needed to yield a superior immunological response, he reported.

Elimination of extraneous and possibly harmful bacterial components is also an important advantage offered by the use of purified antigens, he added.

New Approach

This constitutes a new and rational approach to improvement in antityphoid immunization, Landy asserted. Instances where specific antigenic components have replaced whole organisms are rare; in enteric species we have no such examples, he commented. The present study, therefore, probably represents the first instance of the use of these isolated antigenic compounds in man, he said.

Still to be determined, he emphasized, is whether a combination of isolated antigens shown to be superior to existing vaccines in inducing high levels of antibody will likewise be a more effective means of attaining a high degree of protection against natural infection.

Experimental Evidence

Groups of subjects receiving the bacterial vaccines were given three 0.5 ml. subcutaneous injections of the standard heat-phenol vaccine or the acetone-dehydrated vaccine at weekly intervals and bled 28 and 42 days following the initial injection, he said. The isolated antigens were administered in a single subcutaneous injection containing 20 micrograms of O and 40 micrograms of Vi, and bleedings were taken 21 and 42 days later, he reported.

Individuals having a history of previous immunization with standard heat-phenol vaccine, and who showed preimmunization levels of antibody, responded to inoculation in a manner not significantly different from subjects with no such history or antibody levels, Landy said.

All three types of agents tested engendered acceptable O antibody responses in essentially all subjects, regardless of product received, he said.

The acetone-dehydrated vaccine yielded the least, while the isolated O antigen gave the best O antibody levels, he explained (see figure).

With respect to Vi responses, Lan-

Comparison of Vi (top) and O (bottom) antibody response to three types of antityphoid immunizing agents.

dy reported, low antibody levels (1:7.5 to 1:30) were obtained in 20 percent of the subjects receiving the heat-phenol vaccine, while 75 percent of the subjects inoculated with the acetone-dehydrated vaccine developed titers ranging up to 1:240.

The isolated Vi antigen, however, resulted in 100-percent antibody response, and the titers developed were by far the greatest, reaching as high as 1:960, he asserted (see figure).

Effective Immunity Seen Against Typhus Infection

Experience with an avirulent strain of *Rickettsia prowazekii*, reviewed by John P. Fox, M.D., M.P.H., professor of epidemiology at Tulane University, promises to furnish a vaccine against epidemic typhus.

It appears to require but one inoculation to confer effective and relatively durable immunity in contrast to two or more primary doses and booster shots when typhus vaccines prepared from killed organisms are used, he said. Its advantages will protect military personnel and others when louse control is not effective, he added.

Strain E Found

There have been numerous attempts to immunize man against epidemic typhus by means of living rickettsiae. Vaccinations of this type usually resulted either in no infection and no immunity or in infection associated with unmodified and sometimes fatal disease, he commented.

For this reason, Fox stated, in 1946 Sadusk and Kahlenbeck recommended that living rickettsiae should not be employed for immunization until a strain of demonstrated low pathogenicity for man becomes available.

Fox brought out the following salient points:

In 1943, Clavero and Perez Galardo reported the chance evolution

in embryo passage of a strain of *R. prowazekii* of apparently reduced virulence for experimental animals. This was strain E.

Beginning in 1951 and continuing into 1952, 154 volunteers were given living strain E rickettsiae in varying amounts and by different routes, and an additional 50 volunteers received placebo material or, for comparative purposes, commercially prepared Cox-type vaccine.

Initial interest, of course, centered about the basic safety of strain E for man and the frequency and severity of reactions. Severity and frequency were indicated as directly related to the number of rickettsiae inoculated, but no reactions observed were sufficiently severe to discourage further use of strain E.

It seemed clear that the minimum infecting dose of strain E for man is on the order of 4 log E.I.D.

Study at Parchman

In the work at Parchman, Miss, infecting doses of approximately 4, 5, 6, and 7 log E.I.D. were given by one or another of several routes. There is a direct relation between size of inoculum and maximum level of CF antibody developed within 2 months after inoculation. The relation of immune response to route of inoculation was less uniform. The conclusion reached was that, while intradermal inoculation yielded better results than the subcutaneous route, intramuscular inoculation should be studied further.

Observations as to the duration of serologic immunity, extended over a period of 2 years, are based entirely on the Parchman group. The biggest drop in CF antibody occurred in the interval between 6 and 12 months. The proportion losing detectable CF antibody was greatest in those given smaller inoculums of strain E.

Tests of the actual effectiveness of the immunity in protecting against disease were made by deliberately challenging small groups of volunteers with virulent *R. prowazekii*. No significant clinical dis-

ease followed challenge of these men, even when challenge was given 24 months after strain E infection.

As judged on serologic grounds, immunity induced by strain E will not prove to be uniformly of indefinite duration, and, hence, is not fully comparable to that following natural infection. However, effective resistance to virulent challenge appears to endure for at least 2 years. Also, strain E vaccine seems markedly superior to Cox-type vaccine in point of uniformity of serologic response, of duration of serologic immunity, and of effectiveness in preventing disease after challenge.

Trials in Peru

Extended field trials of strain E vaccine were initiated in Peru in October of 1953.

Vaccinated and inoculated control populations, to number ultimately upwards of 10,000 persons each, are being kept under continuous surveillance in selected parts of the mountainous areas of Peru. With approximately 8,500 persons of all ages vaccinated with strain E as a part of this study, no instance of alarming postvaccination reaction has been reported. Insufficient time has elapsed for significant typhus morbidity data to accumulate.

Successful field use in Peru would seem to dispose of the problem of practicability of application. The most important conditions of successful use probably relate to maintaining the viability of the strain E rickettsiae, both during storage of the lyophilized material and after it has been rehydrated.

A final point worthy of consideration is that of the nature of the interaction between strain E rickettsiae and man. The failure to recover the agent from the blood of infected persons and the direct relation between size of infecting dose and level of sero-immune response are reminiscent of earlier observations as to the behavior of strain E in the guinea pig and suggest that in man also it undergoes little or no multiplication.

A vaccine requiring but one inoculation and producing an effective and long-lasting immunity has obvious advantages for use in military personnel during war and in civilian populations at all times when louse control measures cannot be relied upon or effectively applied.

Varying Booster Responses To Antigens Described

Studies at Letchworth Village in New York State reemphasize the variations in response to reinoculation with different types of antigens, according to the report by Morris Siegel, M.D., M.P.H., associate professor, College of Medicine, State University of New York. These variations, he noted, are important in planning and carrying out effective immunization programs.

Summarizing the pertinent findings, Siegel stated that:

1. An accelerated and very marked increase in circulating antibodies was seen after reinoculation with tetanus toxoid (see chart).

2. An accelerated but somewhat less marked reaction was observed following reinoculation with typhoid vaccine.

3. No increase in antibodies could be detected following reinoculation with pneumococcal polysaccharides until many years after the primary inoculation, when the circulating antibody content of the blood stream was very low or nil.

For the studies of tetanus toxoid and typhoid vaccine, he explained, two groups of 20 male patients each were used, one group having mongoloid characteristics and the other "normal." Two series of subcutaneous inoculations of each antigen were given, the first consisting of 4 weekly doses and the second, 11 months later, a single dose. The period of observation was 33 months.

The rapid secondary response to a single injection of tetanus toxoid

Primary and secondary antibody response to tetanus toxoid.

many years after primary inoculation seems to preclude the necessity of administering antitoxin following minor injury or of repeating an entire series of inoculations, Siegel pointed out in discussing the practical value of the findings of these and other studies.

Under ordinary circumstances, he said, immunity can be maintained at high level by a small booster dose.

He noted, however, that because the secondary response to typhoid vaccine is less marked and less prolonged, the amount of antigen for reinoculation should be larger and reinoculation should be repeated more frequently.

Thus, he stated, reinjection has been recommended every 2 or 3 years under ordinary conditions or every year in epidemic or highly endemic areas.

Host Factors

Variations in secondary response related to host factors were also observed in the tetanus toxoid and typhoid vaccine studies, Siegel indicated. Individual differences, he said, were detectable with each anti-

An individual's secondary reaction pattern to a specific antigen appeared to be reproducible by the use of a single dose, he noted further, but there seemed to be little relationship between an individual's responsiveness to one antigen and his responsiveness to another.

Siegel also reported that regardless of antigen, the mongoloid patients as a group showed lower antibody content in the blood stream than the nonmongoloid patients.

He stressed the fact, however, that even in the mongoloid group, the response to reinoculation was accelerated.

Georgia Rabies Decline Follows Dog Immunization

A rabies epidemic in 1946 covered approximately two-thirds of the State of Georgia but declined abruptly after mass immunization of dogs with living attenuated virus vaccine, according to Leland E. Starr, D.V.M., P.D., public health veterinarian, Georgia State Department of Public Health.

In 1954, only 61 dogs were found to have rabies during the months of January to August, he reported.

He compared this figure with 179 positive reactions during the same period in 1953 and noted that the downward trend continued in 1954. Only 3 infections in dogs were reported in July 1954 and 2 in August.

In 1946 at the height of the epidemic, there were 765 positive reactions from dogs, foxes, and other animals. This figure, Starr continued, probably represents only a fraction of the total number of infections. In the same year, he said, 3 persons died of rabies, and 1,735 were treated.

New Vaccine

Mass immunization of dogs has been one of the main objectives of the control program initiated by the Georgia Rabies Act of 1945. This problem, Starr said, has been greatly simplified by the introduction of a live virus vaccine which apparently confers an immunity lasting for several years.

The killed virus brain tissue vaccine, he explained, conferred a relatively weak immunity and made annual revaccination necessary.

Dog owners disliked both the repetition of the immunization procedure and the abscess or paralysis reaction which occasionally followed it. It was found, Starr continued, that, whenever the incidence of rabies in a community was at a low level, interest in immunization could not be maintained. Reimmunization is not being advocated for dogs which received the attenuated virus vaccine, and the product appears to be free of material which might produce severe allergic reactions.

Starr said that mass immunization programs were conducted in 44 counties during 1952, 1953, and 1954. Living attenuated virus vaccine was employed in all but one of the county projects.

Since 1952, he reported, only one proved case of rabies has occurred in a dog inoculated with the new vaccine.

Fox Rabies

Rabies among the enormous number of foxes in Georgia's forests and swamplands also declined in 1954, according to Starr.

Thinning of the fox population by means of trapping and the payment

of bounties is another primary goal of the State control program, he said.

Starr does not believe, however, that effective and lasting control can be achieved by a few States. In his opinion, only the coordinating activity of a Federal agency can attain that end.

Respiratory System Viruses . . .

The new viruses designated as APC agents are reported as resistant to ether and the antibiotics. Two studies on the RI-67 infections are also reported.

Study New APC Viruses From Respiratory Tract

New respiratory system viruses were reported as having been isolated in tissue culture from adenoid and tonsillar tissue removed at surgery and from nasopharyngeal and conjunctival secretions and feces of persons with respiratory illnesses.

The report was made by Robert J. Huebner, M.D., chief of the Virus Section, and Wallace P. Rowe, M.D., medical officer of the National Microbiological Institute, Public Health Service, and Thomas G. Ward, M.D., assistant professor of bacteriology, Johns Hopkins University School of Hygiene and Public Health.

The new viruses are designated as adenoidal - pharyngeal - conjunctival (APC) agents, indicating the important anatomic sites in which they are found. One hundred forty-three strains of virus have been segregated into six immunological types, and additional types probably exist, they said in reporting that:

All types grow readily, producing similar and unique cytopathogenic effects in human epithelial cells and in HeLa cells available commercially. They are resistant to ether and anti-

biotics. In humans and in rabbits, the viruses produce potent type-specific neutralizing antibodies and lesser amounts of heterotypic responses to other types. Complement-fixing antigens and antibodies produced in comparatively large amounts are group specific but not type specific to about the same extent for all six types.

All six types produce frequent infections in man, beginning at an early age. Serologic surveys in the Washington, D. C., area indicate that 50 percent of infants 6 months to 1 year of age have been infected with at least 1 type. By age 15, the average person has had infections with several types, and by age 34, most persons appear to have had infections with 4 or more types. A few persons were found to have antibodies against all 6 types.

APC Virus Evidence

Intensive investigations are now going on to determine the incidence, prevalence, and specific kind of illnesses produced by these virus infections. Evidence indicates that the viruses of types 3 and 4 cause specific respiratory illnesses. Type 3 has been recovered from numerous cases of acute nasopharyngitis and con-

junctivitis occurring during a winter outbreak on a hospital ward and a summer outbreak in a country day school. Type 4 (Hilleman and Werner's RI-67 agent) apparently produced respiratory illnesses in military personnel described as ARD, primary atypical pneumonia, and acute febrile pharyngitis. Viruses of types 1 and 5 have also been found in cases of acute pharyngitis, but more evidence is needed to establish the role of these and other types in human disease.

A suggested hypothesis is that the APC viruses have a possible role in persistent chronic disease of tonsils and adenoids (and their enlargement). This is based on demonstrations of viruses of 43 strains, classified in 5 immunological types, obtained from persons undergoing tonsillectomy-adenoidectomy and subsequently grown in tissue culture. Possibly more important is the demonstration of viruses in tissues also containing specific antibody against it by the simple expedient of growing such tissues for prolonged periods. This method of "unmasking" viruses represents a highly sensitive and essentially new technique for isolating viruses.

Virus RI-67 Infection Linked to ARD

Studies of respiratory disease epidemics at a number of military bases in the United States revealed widespread infection, especially among recruits in basic training centers, with the recently discovered RI-67 virus group, according to the report of a team headed by M. R. Hilleman, Ph.D., assistant chief, Department of Virus and Rickettsial Diseases, Army Medical Service Graduate School, Washington, D. C.

The other investigators were Capt. H. E. Dascomb, MC, USA, Lt. R. L. Butler, MC, USA, Capt. J. J. McCue, MC, USA, Capt. R. Stragnell, MC, USA, and J. H. Werner.

During the past year, one investigation, based on serum tests, showed that 77 percent of the men in a newly recruited company at Fort Dix, N.J., were infected with members of the RI-67 group of viruses in the first 8 weeks of training, they announced.

About a quarter of the infected men developed illnesses severe enough to require hospitalization. Dispensary treatment was sufficient for another 25 percent of the cases, and half the men apparently suffered very mild or inapparent infections.

The hospitalized patients had illnesses which the Army team said have been called by such names as catarrhal fever, grippé, and virus pneumonia.

Hilleman and his associates claimed that the diseases resulting from RI-67 group infections fit into two clinical entities whose causative agents had not previously been cultivated in the laboratory.

The entities were described as undifferentiated acute respiratory disease, commonly called ARD, and primary atypical pneumonia of the kind in which the test for cold agglutinins of red blood cells remains negative.

Summer Illness

According to the Army investigators, diseases caused by virus RI-67 occur during the warm months of the year as well as in the cold season.

This was said to be in striking contrast to influenza which is common in winter, late autumn, and early spring but quite rare in summer.

A serologic survey taken to determine the extent of previous experience with RI-67 group viruses in the normal human population revealed that a majority of people have had past experience with these agents.

Infection appears to occur most often during the middle years of life, and to be comparatively rare among younger and older people, according to Hilleman and his co-workers.

Virus strains of the RI-67 group were reported to exhibit antigenic

differences which are readily detectable in neutralization tests carried out in tissue culture with serums from human patients with ARD or primary atypical pneumonia. All these viruses, however, elaborated a soluble antigen, common to the entire virus group, which was detectable by the complement fixation test.

The investigators said that these facts made the neutralization test necessary for strain typing and the complement fixation test more suitable for diagnosis.

The Army scientists said that the RI-67 group of viruses are related to the family of latent adenoid and tonsil degenerative viruses discovered in 1953 by Drs. Wallace P. Rowe and Robert J. Huebner, of the National Microbiological Institute, Public Health Service, and others.

Clinical Syndromes Related To New Virus Groups

Determination of the causative agents of certain acute respiratory diseases has opened the way to the study and discovery of the causes of still others, Harold S. Ginsberg, M.D., and his associates reported.

Associated with Dr. Ginsberg in this study of serums from human transmission and clinical cases were: Eli Gold, M.D., William S. Jordan, Jr., M.D., Sidney Katz, M.D., George F. Badger, M.D., and John H. Dingle, M.D., all with the department of preventive medicine of the School of Medicine of Western Reserve University.

The RI-67 agent has been indicated, they said, to be the cause of a grippelike illness called febrile catarrh, or because of its World War II frequency in military populations, "acute respiratory disease of recruits," or ARD. A viral pneumonia may be part of ARD and caused by the same agent, they said. Acute nonstreptococcal pharyngitis, so-called summer sore throat, has been

demonstrated to be caused by at least two of the "adenoid degeneration" (AD) viruses, they said.

Between the relatively mild common cold and the severe primary atypical pneumonia are two infections—ARD and nonstreptococcal exudative pharyngitis. Their exact identification depends upon the recognition of the etiological agent of each, Ginsberg and his co-workers believe. Their study focused on these two infections.

Ginsberg and his associates stated:

1. The agent which produced ARD in previous human transmission experiments was identical with or immunologically closely related to the RI-67 virus isolated by Hilleman and Werner.

2. Susceptibility to infection from this agent was correlated with the absence of specific neutralizing antibodies.

3. Conversely, some resistance to infection was observed in volunteers whose blood contained specific neutralizing antibodies at the time of artificial infection.

4. The RI-67 or related agent did not induce primary atypical pneumonia of the type characterized by development of cold hemagglutinins or the common cold in volunteers.

The report suggested that the agent that causes the grippelike infection be called the ARD virus, but they did not want their findings to imply that the RI-67 agent is the only virus which may cause ARD. On the other hand, they said, the data clearly indicate that more than one agent is responsible for this clinical syndrome.

AD and the RI-67 Agent

Little difference could be demonstrated between the RI-67 agent and the AD type 2 agent when complement fixation titrations were done, Ginsberg and his associates said. The AD agent appears not to be implicated etiologically with the classical forms of ARD or with primary atypical pneumonia, but the evidence

indicates that the type 3 agent is related to nonstreptococcal pharyngitis, and that other agents, one of which is a type 2-like virus, they said, may initiate the disease. They think that in a single, relatively sharp epidemic, more than one agent

may be active; and that neutralization titrations are essential.

One of their findings was that complement fixation titrations cannot be employed to relate the specific etiology of an acute respiratory disease to the RI-67 or AD agents.

Poliomyelitis . . .

Looking to this spring for the report on the Salk vaccine . . . Studying the growth of the virus in the cotton rat fetus.

Poliomyelitis Virus Grown In Cotton Rat Fetus

A new experimental animal, the cotton rat fetus, may now be used to produce and to study type 2 poliomyelitis virus, according to Fred W. Gallagher, Ph.D., department of bacteriology and preventive medicine, University of Vermont College of Medicine.

One of the advantages found in using the fetal brain to propagate type 2 virus is the high concentration of virus produced, he reported.

This high concentration and the large number of fetuses in a single litter makes possible substantial yields of virus material from one pregnant rat, he commented, and this should interest scientists producing virus for antigen in the complement fixation test or for the production of vaccine.

Other advantages Gallagher reported are:

Vaccine made from fetal brain tissue does not produce an encephalomyelitis as adult mouse brain tissue vaccine may when injected into monkeys.

Small quantities of virus in the inoculum suffice to grow large quantities of virus in the fetus. Thus, the fetus might prove to be a delicate

test animal for control use on the inactivation of virus, or for primary isolation of virus from clinical material. Since the virus does not pass from fetus to fetus, several tests may be conducted simultaneously in a single pregnant cotton rat.

Method and Results

Following Woolpert's technique for injecting fetuses, 21-day pregnant cotton rats were used, he said.

The gestation period of the cotton rat is 26 days, and 21-day-old fetuses are large enough for accurate inoculation and yet allow for an incubation period of 4 days, he explained.

In a few cases incubation periods of 2 and 3 days were used, but results were poor, he commented.

Three strains of type 2 virus were used in the experiments, he stated, although most of the work was done with a strain of Lansing virus obtained through the American Type Culture Collection. The other two strains were a Lansing type maintained at the school laboratory for many years by mouse brain passage, and an M.E.F.₁ virus.

Three routes of inoculation were employed, intracerebral, and the thoracic and abdominal cavities, he continued, but the intracerebral route proved best.

In comparative titrations, fetal

brain material was found to contain virus about 100 times as concentrated as the same strain grown on adult mouse brain, Gallagher reported.

Success in the propagation of type 2 poliomyelitis virus in the cotton rat fetus suggests the possibility of growing type 1 and type 3 virus if the right host is found, Gallagher asserted.

Preliminary tests, he added, have indicated that type 1 virus will grow in fetal hamsters.

Report on Salk Vaccine To Be Made Soon

A report on the effectiveness of the Salk poliomyelitis vaccine may be made in the spring of 1955, according to Robert F. Korns, M.D., deputy director of the poliomyelitis vaccine evaluation center at the University of Michigan.

Korns, who is on leave from his post as director of epidemiology and communicable disease control for the New York State Department of Health, reported that 27 research laboratories and 1,800,000 children are participating in the program to evaluate the vaccine. Funds from the National Foundation for Infantile Paralysis are supporting the study.

In addition to painstaking tests concerning children who contract poliomyelitis, blood tests are being performed on samples collected on three occasions from approximately 40,000 other children in the field trial study group.

About 435,000 children in 217 areas of the country have received one or more injections of the vaccine developed by Dr. Jonas E. Salk and his associates at the University of Pittsburgh under National Foundation grants. Another 210,500 have received one or more injections of a placebo. More than 1,175,000 additional youngsters received no injections, but are participating in the vaccine field trial by serving as a control group.

The poliomyelitis vaccine evaluation center at Ann Arbor is under the direction of Dr. Thomas Francis, Jr.,

chairman of the department of epidemiology at the University of Michigan.

Tuberculosis Research . . .

Laboratory studies of the virulence of isoniazid-resistant tubercle bacilli are reported in the two papers in this section.

Report Isoniazid Effects On Tubercle Bacilli

Confirming some findings in recent literature, Robert A. Patnode, Ph.D., and his associates, Martha C. Dail and Paul C. Hudgins, reported that strains of tubercle bacilli isolated from isoniazid-treated patients were found to be less virulent for guinea pigs than typically virulent H37Rv strain. However, they found no correlation between the reduction of virulence and the degree of resistance to the drug in vitro.

Dr. Patnode and Mr. Hudgins are with the Washington (D. C.) Veterans Administration Hospital and Miss Dail is at the Army Medical Service Graduate School of the Walter Reed Army Medical Center. They used 13 cultures from resected necrotic lesions of patients who had received long-term isoniazid therapy (6 months or longer). Dr. Patnode and his associates found the organisms did not differ from the H37Rv strain (used as a control) in their ability to bind neutral red and to form cords or in their ability to decolorize certain oxidation-reduction dyes.

The results of these growth studies, they said, seem to indicate that the organisms have not lost their virulence for guinea pigs solely by virtue of having acquired a special growth requirement for a substance not available in normal guinea pig tissue.

The study, they said, seems to indi-

cate that the altered growth characteristics in vitro and the reduced virulence for guinea pigs are not necessarily based on the same mechanism.

In this experiment, guinea pigs weighing on the average 225 grams were inoculated subcutaneously in the right inguinal region with 0.5 ml. (1.5 mg.) of 15-day-old cultures of the test organisms. Tween albumin medium containing a concentration of isoniazid lower than the minimal inhibiting concentration was used.

Tubercle Bacilli Resistance To Isoniazid Needs Study

The virulence of isoniazid-resistant tubercle bacilli in human beings is still in doubt, although some correlation exists between development of resistant organisms and lack of improvement of patients when isoniazid therapy is continued, reported Daniel Widelock, Ph.D., assistant director, Lenore R. Peizer, senior bacteriologist, and Sarah Klein, bacteriologist of the bureau of laboratories, New York City Department of Health.

Results of laboratory experiments to determine the extent of the risk involved in the spread of isoniazid-resistant tubercle bacilli by unhospitalized patients and the extent to which these organisms are responsible for the maintenance and spread

of active lesions in individual patients accentuated this doubt, Widelock and his co-workers said.

They found that isoniazid-resistant tubercle bacilli played little, if any, part in the formation of tubercles in either guinea pigs or mice when the animals were injected with mixtures of isoniazid-resistant and isoniazid-sensitive organisms. However, the resistant organisms multiplied and produced tuberculous lesions in the lungs, spleen, and liver of guinea pigs with concomitant enteritis. Also, when grown in a drug-free medium, isoniazid-resistant organisms became isoniazid-sensitive in vitro, and when resistant organisms were found in a patient, bacteriological findings became worse.

Further Studies Needed

Widelock and his colleagues said that possibly resistant organisms have no part in the maintenance and

spread of tuberculous lesions in human beings. They suggested that sensitive or only partially resistant organisms may produce the lesions but may not be eliminated by the drug, and that they may multiply as sensitive organisms and maintain the active disease. Resistant organisms, which play no part in the formation of new lesions, may be produced at the same time.

Further study is needed, they stated, to determine the virulence or avirulence of isoniazid-resistant tubercle bacilli. This requires a correlation between clinical findings and a quantitative study of resistant and sensitive tubercle bacilli in the sputum of patients. Widelock and his co-workers are attempting to do this by a quantitative catalase test, considered valuable in the rapid determination of the percentage of resistant and sensitive tubercle bacilli in cultures.

mously when there is actually a significant difference in their meaning.

Common Definitions

McKevitt cited an article in which the terms "performance budget," "functional budget," and "program budget" were all used, apparently interchangeably. "Performance," "functional," and "program" are not pure synonyms in everyday English, he said, although some writers use them synonymously. To question the usage of such elementary terms may seem petty, he stated; nevertheless, "the practical aspects of common definitions should be insisted upon."

According to McKevitt, performance budgeting demands coordination between budgeting, accounting, and reporting. These are general accounting terms which may have to be adapted somewhat if they are to meet the requirements of performance budgeting.

Standardizing definitions is a major accomplishment in any discipline, McKevitt stated. Performance budgeting is comparatively new, and experience will be necessary before refined definitions can be worked out. Several organizations are interested in the problem, and several reports of studies on budgeting and accounting terminology are available or in preparation.

"However," concluded McKevitt, "if we are to reduce the influence of chance in the development of a vocabulary for performance budgeting, we must all be aware of the importance of cooperating in the efforts to develop such a vocabulary systematically."

Business Management . . .

Standardization of the key terms used for public health budgeting is urged, and the use of the fixed-variable technique in controlling public health program costs is explained. Health department savings may be accomplished in a number of ways—one department replaces old automobiles with a pool of leased cars.

Program Budgeting Terms Need Standardization

A happy nomenclature may have more influence than rigorous logic on the acceptance of a new idea, and proper association of words and meanings may be a key factor in the development of understanding of the basic concepts and methods of program or performance budgeting, stated John G. McKevitt, M.P.A., director, administrative services divi-

sion, Michigan Department of Health.

Budget terms and meanings are borrowed from various sources, such as accounting, political science, law, statistics, and taxation, and, in public health programs, from the specialized vocabulary of public health, McKevitt continued. He said that, although most of these terms are well defined and well understood, many are peculiar to program budgeting. Some terms are synonymous, but others are used synony-

Fixed-Variable Technique Tests Costs Behavior

The fixed-variable approach to cost control, a technique being used in industry, is a valuable supplement to sound planning and intelligent control of the cost of public health programs, said Wilson T. Seney, B.A.,

a management consultant, New York City.

Seney defined fixed costs as those incurred in order to be ready and able to do work; variable costs, as those incurred only when work is done. For example, the salary of a roentgenologist is a fixed cost, he said, and the cost of X-ray film varies with the number of examinations made. Fixed costs, he explained, are committed in advance of accomplishing a defined program, whereas variable costs, in contrast, are much more controllable, as they are not incurred until the work is done.

Relating costs to the reasons why they are incurred is the best way to deal with them, Seney said. For example, in a public health agency, the only reason for incurring costs is to achieve some definite result, he maintained. Costs, therefore, should be related to the amount of work done or to the results achieved. Some costs are 100 percent fixed, some are 100 percent variable, and others fall somewhere between these two classifications.

Seney claimed that the fixed-variable technique carries basic budgeting costs to their logical conclusion and helps to plan expenditures in advance and to see that they are used efficiently.

According to Seney, sound cost control means long-range planning, program budgeting, comprehensive budgeting of all costs for each program, techniques to estimate the costs of different methods of doing each job, and individual responsibility for certain costs.

Planning and Performance

Study of the fixed and the variable costs of two proposed programs of equal merit will provide valuable information which cannot be obtained in any other way and which will help in deciding which program is the more desirable from the standpoint of cost, Seney continued. Such a study helps in long-range financial planning; it indicates the cost of a program in more meaningful terms, and it makes possible comprehensive

statements which account for all factors of cost.

Better performance reports are possible with the fixed-variable method of budgeting, Seney said. In a hospital, for example, it is essential to successful performance budgeting that the director be expected to control fixed costs only in terms of living within the fixed cost allowances, but he should be made accountable for variances from the budget allowance for variable costs.

Can't Buy New Cars? Wyoming Leases Them

A new plan providing for leasing arrangements of acceptable and safe transportation was described by Hale Laybourn, administrative officer of the Wyoming State Department of Public Health. The department studied the plan when cut appropriations did not provide enough funds for replacement of old vehicles, Laybourn told his hearers.

The agreement for leasing cars was entered into with a Wyoming firm, after bid proposals. It covers oil changes, lubrication, maintenance, repairs, tuneups, tire replacements, license plates, and 15,000 miles per year for 2 years at a monthly rate of \$65 per unit, with an additional charge of 1 cent per mile for all mileage beyond the set amount. At the present time 11 automobiles are provided by the lease arrangement.

Laybourn stated the average cost per automobile unit since the plan went into effect in September 1953 was 6 cents per mile.

Fleet Rates

The department, Laybourn said, contracted for its own insurance at fleet rates, approximately \$65 per unit per year. Gasoline purchased from State-owned highway garages costs about 20 cents per gallon. An attractive feature of the leased car plan, Laybourn stated, is the personal mileage allowance of one-third

of the 15,000 miles annual allowance to the employee. The driver is charged a flat rate of \$20 per month, \$2.25 per month for insurance and actual cost for all accessories, and 1 cent per mile for all miles driven in excess of the allowed 5,000 miles per year.

Pros and Cons

Laybourn listed these advantages to the State: (1) eliminates the not always successful pool system or assignment of State-owned cars; (2) avoids the need for original capital outlay required in purchasing new cars; (3) eliminates some records, vouchers and purchase orders because maintenance, oil change, lubrication, and tire replacement are shifted to the lessor; (4) obtains safe and good operating vehicles every 2 years; (5) and obtains for the employee economical personal transportation—\$25 to \$35 per month—and for the department, economical transportation costs at approximately 6 cents per mile. Employee morale is improved.

The disadvantages, Laybourn said, include additional auditing and record maintenance to insure that the costs to the department and the miles driven on business are equitable, within the legal limit, and fairly charged.

Problems Remaining

Some problems that remain to be resolved, the administrator thinks, are: (1) Is it better to prorate the charges for personal mileage on a monthly rate or on a mileage rate? (2) Should a different insurance coverage for collision be considered? (3) Can a better arrangement for oil changes, lubrication, and maintenance be applied?

Kansas Estimates Savings From Health Activities

State and local public health activities can be dramatically justified from an economic viewpoint in the

opinion of four members of the Kansas State Board of Health.

Reporting on a study which estimated the savings accomplished by the board were Thomas R. Hood, M.D., M.P.H., executive secretary; Russell L. Culp, M.P.H., chief of the water resources section; Charles A. Hunter, Ph.D., director of public health laboratories; and Bertha H. Campbell, director of health information services.

It is important to the consumer to know whether public funds are purchasing something of value and what return may be expected from the investment, Hood and his colleagues said.

They discussed two methods of approach to compiling data on the economic value of public health services—the calculation of actual savings brought about by public health programs and comparing the cost of a service provided by a government agency with the cost of the same service purchased from private enterprise.

Estimating Savings

Savings may be calculated in several ways, Hood and his colleagues said. Among these are comparison of annual costs of particular diseases over a period of time; listing the cost of judgments against local governments for disease and death following outbreaks of preventable disease; and calculation of the financial savings in insurance claims following a program of health education, early diagnosis, and nursing service among policyholders.

As an example of the economic value of public health activities, they stated that in Kansas, installation of public sewers in new homes simultaneously with construction has resulted in an estimated annual saving of \$2 million in three counties alone.

Another example of the economic value of the contribution of the sanitation division is the \$4.7 million saving resulting from the recovery annually of 1.8 million barrels of oil from waste oil brine.

Hood and his co-workers cited as

other sources of savings through public health programs: control of waterborne diseases; consultation services to cities, schools, and individuals on matters of water supply, sewage and waste disposal, insect and rodent control, general sanitation, and other domestic and municipal

problems; review by engineers of the sanitation division of reports, plans, and specifications submitted by consulting engineers; control of corrosion of water mains and storage reservoirs; control of water pollution; and reclamation of waste products from water.

Venereal Disease Studies . . .

Laboratory examination is the only completely reliable method of confirming gonorrhea, one that will protect the patient and the physician and at the same time be acceptable from a medico-legal standpoint. The reliability of analogies between experimental syphilis in animals and infections in man has been demonstrated in a study of inoculation syphilis at New York's Sing Sing Prison.

Urges Lab Confirmation Of Gonorrhea Diagnosis

With the increase in reported cases of gonorrhea, it is important to know what diagnostic method has been used as a basis for a positive report to the health department, according to Lt. Col. Paul S. Parrino, Capt. Edward J. O'Shaughnessy, and Lt. John D. White. Health departments should insist that the method of diagnosis be stated on all reports of cases of gonorrhea, they said.

Colonel Parrino is preventive medicine officer, United States Army Hospital, Camp Kilmer, N. J.; Captain O'Shaughnessy is urologist and Lieutenant White is research bacteriologist with the genitourinary research project at the hospital.

Information regarding the method of diagnosis has become particularly important during the last 2 or 3 years, they continued, since reports on studies of nongonococcal urethritis in the male indicate that many cases have been erroneously treated as

gonorrhea because of unreliable diagnostic methods. They stressed the importance of uniform diagnostic methods and recommended the universal adoption of the methods described in the American Public Health Association manual, "Diagnostic Procedures and Reagents."

Sufficient funds should be made available to staff all health department laboratories with technicians well trained in the procedures for diagnosing gonorrhea, they stated.

Of the four methods for diagnosing gonorrhea—laboratory, clinical, therapeutic, and epidemiological—only laboratory procedures can be relied upon completely, they asserted, and from the medico-legal standpoint, "complete identification of the gonococcus by cultural techniques is the only method that is acceptable." It is the only one that will protect both patient and physician, Parrino and his co-workers said.

If reliable laboratory services are not immediately available, diagnosis can be made from history and physical examination, but "reliance upon

clinical evidence introduces a very large error," they reported. However, in a high percentage of cases in the male, a correct diagnosis can be made on the basis of differences in length of incubation period, predominant symptom, and character of discharge in gonococcal and in nongonococcal infections.

Diagnosis can also be made on the basis of therapeutic response to penicillin, Parrino and his co-workers stated, but the large proportion of cases of nongonococcal urethritis reported to have been diagnosed originally as gonorrhea but which were not cured by penicillin "is further evidence for more efficient application of recommended laboratory procedures." Also, large doses of penicillin administered to cases diagnosed as gonorrhea without adequate laboratory procedures will contribute to the development of penicillin-resistant organisms, they pointed out.

Sing Sing Syphilis Study Confirms Rabbit Tests

A 15-month well-controlled investigation of inoculation syphilis in man conducted during 1953-54 at New York's Sing Sing Prison confirms many of the findings gained from animal experiments. The study was made possible by the proved efficacy and safety of penicillin therapy for syphilis and by the cooperation of 62 prison inmates who volunteered for the investigation.

The study was reported by Evan W. Thomas, M.D., Lopo de Mello, M.D., Bernard Kaplan, M.D., John C. Cutler, M.D., Harold Magnuson, M.D., and Sidney Olansky, M.D. Dr. Thomas is epidemiologist and Dr. de Mello is venereal disease consultant, New York State Department of Health; Dr. Kaplan is medical officer of Sing Sing Prison; and Dr. Cutler, Dr. Magnuson, and Dr. Olansky are with the Public Health Service's Venereal Disease Branch.

In general, the Sing Sing study

demonstrates the reliability of analogies between experimental syphilis in rabbits and infections in human beings. In the past, any such analogies were subject to question because of the differences between the two species.

Post-Treatment Infection

That reinfection is possible following curative treatment for syphilis was one of the conclusions reached. The study showed that after treatment for early syphilis, reinfection is accompanied by new early syphilis type lesions. Following treatment for late syphilis, some individuals may become reinfected, with development of lesions which, in some cases, were gummatous in nature.

Some of the study group who had been previously treated for latent syphilis may have been protected from the experimental infection by

prior injection of a vaccine of killed *Treponema pallidum*.

Data from the study also suggests that time since treatment may have influenced the possibility of experimental infection in those who had originally been treated for latent syphilis, leading to the implication that immunity to reinfection in this group declines with the passage of time.

Thomas and his associates reported that persons who had been recently treated for latent syphilis were less likely to be infected by the experimental inoculation than were those who had been treated 10 or more years prior to the study. Patients who had been treated for early syphilis could be reinfected experimentally no matter how recently they had been treated. Need for further studies in the development of immunity for syphilis was stressed.

Studies on Brucellosis . . .

A safe, effective test for use in epidemiological studies of human brucellosis is suggested. A new laboratory method for diagnosing brucellosis and a growth factor for a Brucella strain difficult to colonize are described. Attempts to eradicate brucellosis in animals are reported.

Iowa Reports on Control Of Animal Brucellosis

Only the complete eradication of brucellosis in animals will prevent the disease in human beings, declared Stanley L. Hendricks, D.V.M., M.P.H., public health veterinarian, Iowa State Department of Health, Des Moines. In Iowa, he said, brucellosis is the most frequently reported of the animal diseases transmissible to man.

Apparently an increasingly larger

proportion of brucellosis cases result from animal contact and an increasingly smaller number result from drinking contaminated raw milk, Hendricks continued.

Investigations of brucellosis cases in Iowa from the time the first case was reported in 1926 to the end of 1953 also indicate that the skin is important as a portal of entry for *Brucella* organisms, that there is danger of *Brucella* infection when hogs are allowed to mingle with dairy cows, and that *Brucella meli-*

BRUCELLOSIS

Number of sows farrowed, by month, and reported brucellosis cases among male farm workers, by month of onset, Iowa, 1951-53.

tensis occurs in both man and hogs, the veterinarian said.

Hendricks based his report on 2,047 cases of brucellosis reported in Iowa for the 3-year period 1951-53. The cases were scattered throughout the State, he said, but the larger number occurred in counties in which large packinghouses are located.

Of 720 cases for which information on both occupation and sex are available, 51 percent were male farm workers, 22 percent were packinghouse employees, and 10 percent were housewives, he said. More than three-fourths of the housewives lived in rural areas and were exposed to much the same risks as male farm workers. Comparison of the distribution of cases by sex and age indicated that the proportion of male cases is increasing and that in Iowa the majority of cases occur among persons in the 30-49 year age groups.

Seasonal Occurrence

June, July, and August were the months of highest incidence of bru-

cellosis, Hendricks said. The month of onset varied among persons in several occupations, with the most marked variation among male farm workers; about 2½ times as many reported beginning symptoms in June as in January. The number of brucellosis cases among these workers increased in the spring and fall, following the date of sow farrowing by about 2 months (see chart).

Preceding their illness, 80 percent of the persons in the 1951-53 group of brucellosis patients either came into contact with animals or animal excretions in the course of their regular occupation or had such contact outside of their daily work, he said. In several instances, the cases reported apparently resulted from environmental contact, he reported.

The brucellosis patients drank milk from a number of sources, Hendricks stated. Many farm families have pasteurizing units and some of the farm patients used only pasteurized milk bought from a dairy, but 87 percent of those using milk from their own cows drank it without pasteurization, he said.

Hogs, however, are apparently the principal source of *Brucella* infections in Iowa, according to Hendricks, and the approximately 20 million hogs produced in the State each year make up a large potential reservoir of brucellosis.

Iowa is making progress toward the prevention of brucellosis in human beings through the eradication of brucellosis in animals, Hendricks stated. The milk ring test is being used to screen herds of cattle which may contain infected animals; suspected herds are being blood tested; more calves are being vaccinated, and a program for control of brucellosis in swine has been started, with the objective of developing brucellosis-free breeding herds.

Urges Intradermal Tests For Brucellosis Surveys

Intradermal tests, using brucellergen, in epidemiological studies on human brucellosis are safe and are more effective than agglutination

tests for detecting inapparent, latent, and chronic infections, according to a California study. Brucellergen is a protein nucleate prepared from *Brucella abortus*, *Brucella suis*, and *Brucella melitensis*.

The study was presented by Charles M. Carpenter, M.D., Clinton E. Tempereau, M.D., Ruth A. Boak, M.D., Thomas Brem, M.D., George M. Leiby, M.D., Benjamin F. Klauermann, M.D., and Frederick W. S. Modern, M.D., of the department of infectious diseases, University of California School of Medicine, and of the Investigative Medicine Service, Long Beach Veterans Administration Hospital.

Chronic brucellosis morbidity has, as yet, not been satisfactorily evaluated because of a lack of dependable diagnostic methods, they declared.

Data on the epidemiology of human brucellosis have been derived chiefly from reports of cases of acute undulant fever from which *Brucella* has been isolated, agglutination tests on blood of chronically ill hospitalized patients, and agglutination tests of blood submitted to public health laboratories for serologic tests for syphilis, they said.

Intradermal Tests

The dermal sensitivity test for brucellosis has been well-established and resembles the tuberculin test, they declared. The basic problem confronting the investigator, they commented, is the differentiation of immunity from active infection in persons with dermal sensitivity.

Tests for the present study were made by injecting 0.1 ml. of brucellergen intradermally in the forearm and results were read after 48 hours, they said. The authors reported they experienced no difficulty with false-positive reactions or severe reactions from those patients with marked dermal sensitivity.

The results of the present study fell in line with the studies reported in the literature, they commented. Findings reported were: Of 900 hospitalized patients tested, 223, 24.8

percent, reacted positively; 53 well persons of 500 tested, 10.6 percent, were positive; 73 Tahitians, never previously in contact with the infection, all reacted negatively; only 3 of 100 hospitalized children reacted positively.

Brucellosis Test Method Gives Uniform Results

Microscopic slide and macroscopic tube flocculation tests for brucellosis, which give clear and easily read results, can be performed rapidly and can be reproduced in any laboratory, according to Charles A. Hunter, Ph.D., director, and Bernice L. Christesen, B.S., division of public health laboratories, Kansas State Board of Health.

A newly developed method for coating cholesterol with *Brucella* organisms or extract produces an antigen that can be adjusted to standard sensitivity and specificity, they asserted.

Since the use of cholesterol coated with cardiolipin and lecithin as an antigen has made it possible to standardize serologic tests for syphilis, Hunter and Christesen believe a similar process can produce a standardized test for brucellosis and decrease mistakes in interpretation of titer. They do not believe that the use of one particular strain of *Brucella* will produce an antigen for a standard test.

Antigen emulsions prepared by the new method may be used immediately or for at least 8 days after storage under refrigeration, they said. Microscopic and macroscopic flocculation tests have been compared with agglutination tests using this antigen and their results are easier to read and give a sharper end point than tests generally in use, they reported.

Contrary to recommendations in current agglutination techniques, Hunter and Christesen found that inactivation of the serum at 56° C.

for 30 minutes reduces prezone reaction and produces results which are relatively clear and easily interpreted.

It is doubtful that interpretation of results obtained from agglutination tests can ever be standard, they said. But, they added, flocculation tests, which may be adopted in standard form in any laboratory, using antigen produced by this new method, may eliminate most of the difficulties experienced with present agglutination techniques.

Growth Factor Found For Fastidious *Brucella*

Discovery of a biochemical agent which promotes the colonial growth of a fastidious *Brucella* strain was reported by I. Forest Huddleson, D.V.M., Ph.D., of the Michigan State College Department of Bacteriology and Public Health. He identified the agent as an albuminous substance or one closely associated with this fraction.

Huddleson, in attempting to find a medium to promote the growth of the CO₂ dependent type II (Wilson) strain *Brucella abortus*, used three agar and liquid media—tryptose, trypticase soy, and peptone M. His experiments revealed that the growth factor is contained either in a completely soluble extract from sonically disintegrated cells of *Brucella suis* or *Micrococcus aureus*. It can survive a heat of 120° C. for 30 minutes.

Demonstration of the factor, he indicated, makes possible the isolation of *Brucella* strains from infected humans and animals. As a result of its presence, agar cultures of tryptose and peptone M were converted from unsatisfactory to highly satisfactory media.

Huddleson experimented with killed and living cells of *Brucella bronchiseptica*, *Salmonella pullorum*, and *Salmonella typhosa* (Vi type) in addition to *B. abortus*, *B. suis* and *M. aureus*. He extracted

dense cell suspensions of the latter two micro-organisms by sonic disintegration in a magnetostriiction type of apparatus kept cooled to 15° C. by flowing tap water. He then separated the extracts into purified and crude fractions by (NH₄)₂SO₄ fractional precipitation and tested the

fractions for growth possibilities on the various media. Except for pH adjustment, the media were prepared according to the manufacturers' formulas. Preliminary studies of the purified fraction indicated the chemical nature of the growth factor.

for 14 years or more for foremen, craftsmen, operatives, and laborers occurred significantly more frequently in the lung cancer group than in the control group, they explained.

Individuals employed in the significant occupations comprised 45.3 percent of the lung cancer cases and 27.8 percent of the control group, they reported. It appears that the excess risk attributable to occupation among persons in various smoking categories ranges from 1.5 to 4.3 times the risk in nonsignificant occupations, they said.

It would also appear from these tabulations that occupation exerts the least effect on heavy cigarette smokers and that heavy cigarette smoking exerts its greatest effect on occupations not associated with lung cancer, they commented.

Cancer Research and Control . . .

Occupation does not seem to be directly related to lung cancer incidence among smokers. Cobalt⁶⁰ beam therapy is discussed, and the value of cancer public education programs is assessed. The contribution of epidemiology to etiology is the subject of still another report in this series of papers.

New York Studies Cancer Factors in Occupation

The possibility that the factor of occupation does not account for the higher incidence of lung cancer among smokers was indicated in a study of the occupational histories of cancer patients at Roswell Park Memorial Institute.

The study also indicated that the excess of lung cancer attributable to several specific occupational groups cannot be explained by smoking.

The study was sponsored by the New York State Occupational Cancer Committee. The report was presented by Morton L. Levin, M.D., Arthur S. Kraus, M.S., Irving D. Goldberg, M.P.H., and Paul R. Gerhardt, M.D., who serve, respectively, as assistant commissioner for medical services, acting associate biostatistician, senior biostatistician, and director of the bureau of cancer control of the New York State Department of Health.

Study Conditions

One-hundred thirty-seven male lung cancer patients, and a control

group of 396 cases with nonrespiratory cancer, which had an age-residence distribution equal to that of the lung cancer group, were studied, they explained.

The study, they said, was made primarily to find clues for further study of occupations with an apparent excess risk of cancer of various types. The patient's occupation history included all previous employment.

A team of industrial chemists compiled a list of probable exposures to various chemical and physical agents, including suspected carcinogenic agents. Thus, specific information from the patient and the judgment of industrial chemists were used in determining possible exposure to various physical and chemical hazards.

Results, Discussion

Out of 18 major occupation groups, two, the metal trades and the construction industry, occurred significantly more frequently at the 0.05 percent level in the lung cancer group than in the control group, they reported. Exposure to free silica and to iron dust and excessive heat

Cobalt⁶⁰ Beam Therapy Aids Cancer Patients

Patients suffering from some types of inoperable lung, rectal, and bladder cancer can expect a better chance of cure from extensive research with cobalt⁶⁰ beam therapy, said Ivan H. Smith, M.D., director of the Ontario Cancer Foundation, London Clinic, Victoria Hospital, London, Ontario.

This new form of irradiation, he continued, also promises longer life and reduced suffering for patients with incurable rectal, gastric, and pancreatic cancer. Another use of cobalt⁶⁰, he predicted, will be in connection with surgery, particularly as a postoperative technique.

Smith made an interim report on 1,149 cases treated since the clinic began its clinical investigation on October 27, 1951. No conclusive results can be given for the new method of treatment, he said, since cancer cures aren't regarded as certain until the patient has lived for 5 years after therapy.

He referred to the response of lung cancer patients to cobalt⁶⁰ as "most

gratifying and often dramatic." The treatment was beneficial, in some degree, to 50 patients, 72.5 percent of the 69 cases treated, 70 percent of whom were in an advanced stage of the disease. Three of them are living 24 months after treatment and 27 have survived for 4 to 16 months, he reported.

Rectal Cancer

It is Smith's opinion that in some cases of rectal cancer, cobalt⁶⁰ offers a palliative alternative to surgery for a limited group of elderly patients or "the odd cantankerous rogue" who refuses to have an operation. Improvement was seen in 25 patients or 75 percent of the 33 cases available for study. In most of them the disease was either advanced or had recurred after other forms of treatment. This is one of the forms of cancer for which Smith recommended the use of postoperative cobalt.

Smith said that cobalt has brought relief from pain and restoration of appetite to 10 out of 20 frail or elderly individuals with inoperable stomach cancer. Six of them are living 5 to 16 months after treatment. As a rule, the improvement is temporary, he said, and is followed by a later return of symptoms. He believes, however, that X-ray rotation therapy and a combination of chemotherapeutic agents should hold additional promise.

Cancer of the larynx is another type of malignancy for which Smith recommended cobalt⁶⁰ as the initial form of therapy with reliance on surgery if the disease recurs. He has also, he said, obtained worthwhile results with cobalt⁶⁰ in cases of oral cancer, relying on surgery in the event of complications or recurrences.

Cobalt Advantages

The advantages of cobalt irradiation over conventional X-ray treatment, according to Smith, rest in the fact that a greater dosage of rays can be directed to tissues and organs in the interior of the body with less

danger to surface and other intervening tissue. He also believes cobalt enables patients to tolerate a greater dose of irradiation to a particular organ and the body in general in a shorter time.

There is still, however, a narrow breach between the amount of irradiation from any source which can be tolerated by normal tissue and the dosage necessary to cause lethal tumor damage, said Smith. The radiotherapist's major clinical problem today, in his opinion, is to find chemotherapeutic agents which will widen that breach.

Any form of irradiation, he said, is futile against widespread cancer, except for the temporary relief of symptoms, and then conventional X-ray therapy will bring the desired results. Leukemia and Hodgkin's disease are outside the cobalt realm, he stated.

Cancer Morbidity Studies Test Etiological Theories

Although the incidence rate for all forms of cancer is almost identical for each sex, men run a 60 percent greater risk than women of developing common forms of cancer, except malignancies of the breast and genital organs, reported Harold F. Dorn, Ph.D., chief of the Office of Biometry at the National Institutes of Health.

However, until age 50 is reached, the incidence of cancer of the reproductive system among females exceeds the incidence of all forms of cancer among men, he said, using data from morbidity surveys conducted by the National Cancer Institute in selected urban areas of the United States in 1947 and 1948. The rates were adjusted for age to the total population of the country in April 1950.

Nearly one-half of all cancers among women originate in the breast or genital organs, he continued. In contrast, only 1 in 8, or 12 out of every 100 males who develop a malignant neoplasm, will have cancer of the genital organs or breast.

All other common forms of cancer occur more frequently among males than females, he stated. Excluding malignancies of the reproductive system, the incidence rate per 100,000 population becomes 290 for men and 181 for women.

Use for Etiology

Dorn presented these statistics as an example of the use of morbidity data in the study of disease causation. Epidemiology is one of the tools used in etiology, he explained. The first step in the epidemiological process is an accurate description of the way a disease manifests itself in different population groups and subgroups and environmental situations.

The principal objective, he said, is to collect morbidity data for the purpose of formulating a hypothesis about causation, since the facts take on meaning only after they are organized and related to some theory. For instance, the fact that males are more likely to develop any form of cancer, except malignancy of the reproductive organs, suggests that they are more susceptible to cancer than females or that as a group they are more exposed to environmental carcinogenic agents.

Morbidity data, he continued, support the belief held by clinicians in the dependence of breast cancer development on the functioning of the endocrine system. Physiological changes associated with menopause, possibly hormonal in origin, temporarily slow up the rapid rate of increase in the incidence of breast cancer that is found prior to this age period. The strength of the association varies among different population groups and appears to be more marked among single women, according to Dorn.

Cervical Cancer

For many years, Dorn said, clinicians have reported that cancer of the uterus was much less common among Jewish than among non-Jewish women and that cancer of the cervix uteri was exceedingly

rare, almost nonexistent, some thought. Preliminary results of comparative morbidity studies in Israel and New York City showed that the incidence of uterine cancer among Jewish women in Israel is less than one-half that among white women in the United States, Dorn reported. The incidence of corpus cancer is approximately the same for both groups, but cervical cancer was found about one-sixth as frequently among the Jewish women as among white women in this country.

The last finding indicates, he said, that cervical cancer, although infrequent, is far from rare among Jewish women. The difference between Jewish and non-Jewish incidence of all varieties of female genital cancer is real but not as great as formerly thought. Moreover, important variations in the incidence of genital cancer, he went on to say, were found within the Jewish population itself, which suggests that existing etiological theories may need to be examined and tested.

Dorn gave these examples to illustrate the epidemiological contribution to etiology. This, with knowledge gained from clinical experience and animal experimentation, can be components of hypotheses of causation, which must be tested by new clinical and epidemiological studies.

Recognition of Symptoms May Delay Diagnosis

Do cancer education programs which spread a knowledge of symptoms cause the very thing they are trying to avoid—a failure to have the disease diagnosed in its earliest and usually most curable stage?

Consideration of this question is suggested to the Nation's health departments by Rose K. Goldsen, Ph.D., research associate in the Cornell University department of sociology and anthropology.

Goldsen believes that an ability to recognize the signs of cancer increases the anxiety of chronic worriers about the disease and makes

them delay any possible confirmation of their fears. Cancer knowledge has its desired effect only on persons who, aside from concern over a definite symptom, aren't particularly anxious about malignancy, she said. The appearance of a danger signal sends them to a physician immediately.

However, in Goldsen's opinion, familiarity with cancer symptoms isn't the deciding factor in early or late diagnosis. Good general medical habits seem much more important, she stated. People at all levels of cancer knowledge are much less likely to neglect possible signs of malignancy if they habitually consult a physician as soon as they become aware of the symptom of any disease.

Goldsen based these conclusions on a study conducted in 1951 and 1952 by Cornell University's social science research center under the sponsorship of the division of medical services of the New York State Department of Health. Interviews were held with 727 persons who visited tumor clinics and cancer detection centers for the diagnosis of conditions which might be cancer symptoms. Individuals who had postponed an investigation of their symptoms for 3 months or more were classified as delayers and were contrasted with people who had gone for an immediate checkup.

Major Finding

The major finding was that delay in seeking diagnosis for an observed danger signal of cancer is a special case of chronic patient delay, Goldsen reported. Reaction isn't governed primarily by the implications of this particular symptom, but by the sociomedical habits, attitudes, and practices of a lifetime. Goldsen said that over half the patients who admitted that they had put off a needed medical examination in the past also postponed their visits to the tumor clinic. Only 15 percent of those who did not admit earlier procrastination were delayers in seeking cancer diagnosis.

Another finding, confirmed by other investigators, was that an inconspicuous cancer symptom brings persons in for diagnosis more quickly than an obvious one. This finding is one aspect of the relationship between reaction to cancer signs and good general medical habits, said Goldsen. The likelihood of extreme diagnostic delay is more than tripled if individuals who customarily postpone any medical examination or treatment notice a very obvious symptom, she continued. The chances that such a person will be a delayer are 52 in 100. On the other hand, the study found that when a person with good medical habits becomes aware of a hidden sign, the chances of delay are only 15 in 100.

Additional Findings

Other factors in delay include self-diagnosis and a suspicion of cancer in the past. Also, persons who feared their condition might be "something serious" were less likely to delay diagnosis than those who diagnosed the symptom differently. Goldsen also reported that if a person had feared cancer in the past and found his suspicion unjustified, he was less likely to seek professional examination for a new symptom or a recurring one. This didn't apply, however, to persons who usually see a physician for any symptom.

Goldsen didn't find that cost considerations have much influence on delay. She did, however, find a link between delay in seeking professional advice and reluctance to discuss the cancer sign with everyday associates. Diagnosis was deferred by 45 percent of these reticent persons, she said, whereas only 29 percent of the less reserved were delayers.

Other factors influencing deferral are residence in rural areas and low educational and economic status, Goldsen reported. Indifference to one's unemployment also produces delay.

But the patient's general medical habits will either minimize or intensify all other factors. In Goldsen's

opinion, the problem of cancer delay should be approached by public health educators, not by stressing the knowledge of cancer signals, but by emphasizing the need for prompt medical response to the symptom of any disease.

Public Cancer Awareness Brought Wider Attack

The American Cancer Society's public education program—the reason for which the organization was formed in 1913—succeeded so well that cancer consciousness among laymen increased more rapidly after that date than the ability of physicians to recognize tumors smaller than they had been seeing, said Charles S. Cameron, M.D., the society's vice president and medical and scientific director.

As people learned more about malignancy, he continued, the dangerous period of delay before diagnosis was reduced; diagnosis became more difficult for physicians, and the need for a program of professional education became apparent.

Greater public awareness of cancer, he said, also meant increased demands on clinical services, called for an expansion in medical social services, and showed a need for nursing care of patients in their homes.

Broadened Program

Services of this kind could not be offered directly by the society, Cameron said, but existing professional agencies, such as clinics and nursing services, could be encouraged by financial aid, and new professional activities could be inaugurated by subsidies from society funds. Its present program of professional education, for instance, includes—in addition to publications and cancer seminars—fellowship grants for formal postgraduate training in cancer diagnosis and treatment.

The development of cancer clinics, where complex problems of cancer

diagnosis and case management are supervised by relatively small staffs, is another example of ACS efforts to meet increased demands for cancer services, according to Cameron. The society, he said, recommended the establishment of these clinics in 1929. The American College of Surgeons was invited to provide standards for the clinics' operation and certify those which qualified. There are now over 600 cancer clinics in the country, Cameron reported, and about two-thirds of them have been or are now being assisted by society funds.

Patient Services

The service program is conducted at the local level by the society's divisions and units, within the limits

of broad national policies adapted to local needs, the speaker continued. Over 2,000 information centers are available to help the cancer patient and his family. Drugs, medication, and dressings may be provided, he said, and more than 250 articles of sickroom equipment, such as hospital beds or wheelchairs, may be loaned to needy patients.

Research Grants

In 1944, the society was reorganized and its base of activity broadened to include the support of basic and clinical cancer research, Cameron reported. In 1953, it supported 283 specific projects in 111 institutions and 41 mass, or institutionwide, grants to 41 laboratories and universities.

Childhood Accident Prevention . . .

Epidemiological studies of accidents among children to learn more about how, where, when accidents occur are urged as a basis for effective prevention programs. The results of one such study are reported. Other approaches to childhood accident prevention discussed include Chicago's poisoning control program and New Jersey's experiment in mass safety education.

Proposes Dynamic Program Against Child Accidents

An epidemiological approach to the prevention of children's accidents, accompanied by a dynamic and continuous safety program, was urged by Ross A. McFarland, Ph.D., associate professor of industrial hygiene, Harvard School of Public Health.

Pointing out that 15 percent of all accidental deaths occur among children under 15, McFarland urged parents, educators, physicians and others to cooperate in education and training efforts and to help modify emo-

tional responses in children that may contribute to accident proneness.

McFarland held that accidental injuries and deaths follow some of the same biological laws as do disease processes and are amenable to controlled experimental studies, epidemiological surveys, and statistical analysis. Chief advantage of the epidemiological approach, he stated, stems from complex investigation of multiple causation.

Accident reduction may be accomplished through attention to the analysis of interaction of forces having to do with the host, the agent, and the environment. Prevention programs should begin with attempting

CHILD ACCIDENTS

to control or modify those characteristics of the child which have been found to be important in causing accidents, he indicated.

Accident Data

Such a program, McFarland stated, should begin with data on children's accidents: Who had them? When? Where? How did they occur? What were the circumstances? What characteristics of the child contributed to the accident? What behavioral indexes identify the child as one who may be unusually susceptible to accidents? What is the influence of other variables such as emotional upsets, feelings of rejection and non-acceptance, desire for parental attention, fatigue? What is the role of diet and blood sugar levels?

McFarland pointed out that reducing children's accidents through attention to the agent can be accomplished by isolating the host from the agent and reducing the virulence of the agent. Analysis will show that certain types of agents are involved in children's accidents more frequently than others, he said. These shift in emphasis with advance in age. He cited kerosene, lead poisoning, strangulation, and flammable clothing as examples.

Training in the recognition and avoidance of hazardous situations becomes especially important as the children become older, he said, pointing out that safety education should aim at safe practices without unduly restricting the natural proclivities of the child. Another approach toward reducing hazards calls for engineering and designing of equipment used by children, keeping in mind the age group for which equipment is intended. McFarland mentioned the design of harnesses and sleeping gear for infants as a case in point.

Control Bases

Further analysis of accidents within the places they occur, by agent, type of accident and type of activity at the time of the accident,

yields specific clues as to the role of environmental factors and affords control bases.

Referring to the icebox deaths in the United States, McFarland pointed out that there are no reliable data on the frequency of these accidents. He stated, however, that these accidents afford a clear example of accidents which can be prevented through environmental control, either through the design of equipment for safety—doors which can be opened from the inside—or through modification of existing hazards by removing doors from discarded boxes.

The control of social forces which influence the incidence of accidents appears to lie in the provinces of educational and emotional hygiene, whether applied to parent-child relationships or to the social climate of play or school groups, McFarland concluded.

Epidemiological Patterns Revealed in N. Y. Study

At least 92 percent of 120 fatal accidents in 1953-54 among children under 6 years of age could have been prevented, according to an epidemi-

ological study made by the New York City Department of Health.

Reporting on the study were: Harold Jacobziner, M.D., assistant commissioner, maternal and child health services; Patricia I. Heely, director, bureau of public health nursing; and Herbert Rich, senior statistician, bureau of records and statistics.

Pointing out that effective accident prevention programs must be based on facts concerning accident causation, they emphasized the need for employing epidemiological techniques in this field. Accidents follow a distinct epidemiological pattern, they declared, maintaining that the epidemiological approach should be as effective in controlling accidents as it has been in combating many infectious diseases.

In the New York study, Jacobziner and his associates specified, home visits were made by public health nurses to find out how, where, when, and to whom accidents occurs. They reported the following "unmistakable facts" from the study:

1. The highest incidence of fatal accidents was in children under 1 year of age, and the most frequent cause was so-called mechanical suffocation (see table).

2. Falls caused the second largest number of accidental deaths. They

New York City Department of Health accident fatality study: cause of accident by sex, race, and age

Cause of accident	Total	White			Nonwhite			Age in years					
		Total	Male	Female	Total	Male	Female	Under 1	1	2	3	4	5

were most frequent in the early ages, from less than 1 year to 3 years, and during the summer months.

3. Traffic accidents were most frequent at the active ages.

4. Completely without adult supervision when the accident occurred were 62.5 percent of the children.

5. A definite correlation was found between incidence of accidents and socioeconomic level of the family, the incidence being higher in the underprivileged areas.

6. Accidents were more common among boys than among girls and among nonwhite children than among white. (Twenty-six percent of the accidents occurred in the nonwhite population, but the nonwhite population is only 16 percent of the total population.)

7. Only five children had a definite history of previous accidents, indicating that "repeatism" is probably not established as a pattern at ages under 6 years.

The study also investigated handicapping conditions of the child and emotional and mental disorders of the parents as possible predisposing factors, but the evidence was inconclusive, they reported.

Public Health Nurse's Role

In the opinion of Jacobziner and his associates, the public health nurse is the most logical choice to make home visits for a study of this type. Their reasons were these: She has intimate knowledge of the area involved and its people; she has had training and experience in establishing easy liaison and rapport with families; she can use the home visit for general public health instruction and guidance, as well as accident investigation.

Poison Control Program Launched in Chicago

A poisoning control program, designed particularly to aid children who accidentally swallow household substances that may be poisonous,

has been in successful operation in Chicago for over 10 months, according to Edward Press, M.D., M.P.H., and Robert B. Mellins, M.D.

Dr. Press is chairman of the Chicago Poisoning Control Committee and is also associate director of the division of services for crippled children, University of Illinois. Dr. Mellins is an epidemiologist at the Communicable Disease Center, Public Health Service, on loan to the Chicago Board of Health.

The Chicago program is the first of its kind in the country, Press and Mellins reported. Centers in Boston, Cincinnati, Dallas, New York City, Phoenix, and Washington, D. C., have begun operating or are ready to start, they said. The Chicago group will act as a central agency for the collection and interchange of information.

Program Activity

The Chicago program coordinates the efforts and resources of 20 hospitals, 5 medical schools, 4 full-time health departments, and others in a centrally guided plan for the treatment and prevention of accidental poisoning.

Press and Mellins stressed the importance of a looseleaf reference guide to the toxic constituents of thousands of household substances. The guide also outlines recommended treatments for patients who accidentally swallow any of these substances. It is made available to individuals and institutions affiliated with the program. Physicians in the emergency rooms of hospitals are free to modify the suggested treatments in accordance with their own best judgment.

The data on all cases treated, including the material swallowed, the major signs and symptoms, the treatment, and the results, are sent to the Chicago Board of Health on a form specifically developed for the program. These reports are analyzed and then summarized, Press and Mellins said, and the information is reported periodically to participating centers.

Members of the health department

make home visits or telephone calls, or both, to the families of children treated under this program. The visits are made primarily to help correct the conditions that led to the accidental swallowing of poison, but they also help to complete information on the type and amount of poison swallowed and on results of treatment. These contacts, they said, afford an opportunity to recommend general public health measures to the family and to leave home-safety checklists.

Program Results

In the 10 months of the program's operation, 375 patients have been treated for swallowing a variety of substances—rat poison, kerosene, turpentine, insecticides, bleach, and lye, they reported. Only one death occurred.

Press and Mellins believe home visits to be effective in alerting the public to the danger of home accidents. Although admittedly a subjective evaluation, they felt that 131 of 147 home visits resulted in corrective measures that may prevent future accidents.

Fear Used to Educate May Arouse Anxieties

When ought fear to be used to induce a population to adopt healthy practices?

Paul V. Lemkau, M.D., Johns Hopkins University School of Hygiene and Public Health, in his discussion of safety education without fear, stated that only when medicine has something to offer in the way of prevention should fear be used to motivate.

"When there is no technique available, when knowledge on which to base action does not exist, fear seems a weapon that has its dangers for the mental health of the people," he said, pointing out that fear was all right to use in typhoid fever campaigns since the disease can be stamped out. But he doubted the value of its use in

campaigns in which research is the only escape that can be offered to the anxieties of the populace.

Lemkau differentiated between anxiety and fear. Healthy fear, he said, of a dangerous situation about which something may be done may reduce its dangers. He declared that accidents are predictable events and to label them as accidents is a semantic error.

"Were accidents really accidents, we could have no preventive program," he said. "It is because they are events that are to some extent predictable, that we can analyze the various factors entering into the determination of their predictability and do something about them. Such analysis produces understanding and has the effect of reducing anxiety and healthy fear since the dangerous situation can then be better controlled," he said.

Accident prevention as a public health endeavor is fortunate in that the mechanics of accidents can be known, he continued. The cause and effect relationships are easily grasped, the factors of predictability offer the opportunity to reduce both fear and anxiety through their modification, and the fact that most people want to reduce accidents, at least consciously, makes the atmosphere favorable to accident prevention.

Zindwer described the project, in which approximately 40,000 persons participated and all local health units cooperated. She reported:

Preceded by an intensive campaign in which 1,191 local PTA units were alerted, a multiple-choice questionnaire was distributed to a 10-percent sample of parent-teacher membership throughout the State. Approximately 83 percent (25,000) of the questionnaires were returned.

The questionnaire was developed with the assistance of the APIA professional examination service. Its 16 questions theoretically involve the respondents in situations common to the home and which are potentially hazardous to a small child. Pretesting demonstrated that the questionnaire was a powerful health education tool because people reacted emotionally to the extent that they were eager to debate the issues presented (see sample question).

Distribution of the questionnaire was augmented by local radio and newspaper publicity. A Rutgers University radio forum on child safety was rebroadcast over 17 radio stations. Eighty-three articles and nine editorials appeared in 55 newspapers.

Followup of the questionnaire so far has consisted in its discussion

at PTA meetings, publication of the preferred answers with reasons for their choice in the monthly publication of the State Parent-Teacher Congress, and similar publication of one question a week in the form of a child safety quiz in 28 newspapers. Similar radio coverage is planned.

Incomplete returns from an evaluation questionnaire sent to the various PTA chairmen indicates that local and county safety programs are scheduled. Other groups desire the safety questions for discussion. Requests are being received for the tabulation of answers, still to be completed, as well as for additional educational materials. A more detailed evaluation will obtain information on how local PTA chapters received the project and what specific plans are being made for further educational activities.

The New Jersey State Department of Health, Medical Society, Parent-Teacher Congress, Safety Council, the American Academy of Pediatrics (State chapter), and the National Safety Council are sponsors. The health department's actual cash outlay was \$300. Other costs have been borne by the sponsors, but the major cost was defrayed by the volunteer man-hours donated. The National Safety Council is doing the statistical processing.

An Experiment in Safety— The New Jersey Project

Because home accidents among young children warrant special attention, New Jersey undertook an experiment in mass safety education during the spring of 1954.

By investigating the judgment and attitudes of adults in relation to these accidents, a new approach was made toward translating already existing knowledge into preventive action, according to Renee Zindwer, M.D., M.P.H., chief, bureau of maternal and child health, New Jersey State Department of Health.

Sample Question

The Howards realize that children must not only be protected but should also begin to learn about possible dangers as soon as they can understand. They believe that they can best begin teaching their Johnny (18 months) the meaning of the word "hot" by:

1. Saying "hot" while allowing him to touch something just warm enough to startle him so that he will understand the word "hot" when used as a warning.
2. Saying "no, no, hot!" to him and pulling him away each time he approaches any hot object such as a heater, a stove, or a heated iron.
3. Repeating the word "hot" and spanking him whenever he gets dangerously near a hot object which may injure him.
4. Demonstrating the meaning themselves by pretending to touch a hot object quickly and then exclaiming "ouch, ouch, -hot!"

Birth Certificate Data . . .

Of interest to consumers of information obtained from birth records are the experiment in improving the quality of vital statistics which is now under way in several States, and the problem of inaccurate reporting which one health department found when it surveyed current obstetric practice in the community.

Vital Statistics Methods Important to Consumers

Changes in the methods of producing national vital statistics are important from the consumers' viewpoint as well as the producers', declared Howard West, M.P.H., chief of the biostatistics and health education division, District of Columbia Department of Public Health.

Under new procedures, several States are coding birth certificates and furnishing punched cards for tabulation by the Federal Government. West called this experiment "the most far-reaching and fundamental step" thus far to speed production and to cut costs, but he indicated that it may create problems for consumers of the data.

The selection of items that should be included on the punched cards previously was the responsibility of the National Office of Vital Statistics. This function will be increasingly shared with the States, West noted. Whether in the long run such joint consideration will benefit consumers cannot be answered now, he commented. Other questions relate to whether comparability will be maintained in interpretation, in classification, and in the carrying out of the numerous other statistical processes.

West asserted that a quality control procedure for the State-prepared cards would appear to be basic. He warned that selection of a State's birth records for one month as a sample for quality control would not be adequate to discover significant errors or provide means for their cor-

rection. For this reason and to facilitate special studies by the NOVS, he indicated that copies of all the records should be made available.

State Preparation of Tabulations

West also urged consideration of the gains and losses to the data that can be anticipated if States prepare birth tabulations for use in producing national statistics.

He suggested two possible gains: earlier publication of national statistics, if all States tabulate simultaneously and maintain the schedule; and improvement in the quality of State staffs and in the caliber of State vital statistics activities. On the debit side he noted these problems: quality control, rigidity of tabulations, and lack of data to satisfy unanticipated needs for national statistics.

Study Shows Inaccuracy Of D. C. Birth Certificates

Problems of under-reporting and over-reporting on birth certificates handicap the District of Columbia's obtaining a true picture of its current obstetric practice.

This was the reaction of Ella Oppenheimer, M.D., director of the bureau of maternal and child health, District of Columbia Department of Public Health, after a 1952 survey of birth certificates and matching hospital records revealed these chief deficiencies. The hospital records were assumed to be correct.

As part of a more detailed study to improve standards of maternity care, the investigation of matching records was devised to test the adequacy or accuracy of 24 items on the official birth certificates.

The selected items, some of which appeared on a detachable medical information supplement to the certificate, included: length of gestation, birth weight, type of delivery, need for artificial respiration of the infant, complications of pregnancy and labor, duration of labor, and the occurrence of congenital malformations and birth injury.

Birth weight, Oppenheimer said, was the only item reported with 98 percent completeness and accuracy. Length of gestation was found grossly inaccurate, with an extraordinary concentration of births in the 40-week category—76 percent as compared with 19 percent on comparable hospital records.

In one hospital with a study sample of 148 births, none was specified on the birth certificate as requiring artificial respiration, whereas the medical records showed 29 required it, she reported.

Oppenheimer said the health department can correct incompleteness of response by a conscientious inquiry into the reasons for such deficiencies. Since the reporting of this information is required by law, failure to comply cannot be well defended by the hospital or physician, she declared.

A program of enforcement could help, she said. Better cooperation, she added, can be expected from physicians if the reporting is simplified, if it is known that the data reported are being used, and if the value of these data is demonstrated through the dissemination of periodic reports of the findings.

Inaccuracy of response is a more difficult problem, demanding careful revision of the wording of items, as well as orientation in the meaning of the terms employed, she continued. The medical information requested on the birth certificate should be such that it can be reasonably obtained by the hospital staff

and appears to have relevance to the current problems of maternal hygiene.

The medical supplement to the birth certificate must not be permitted to become a fixed part of this vital record in terms of its contents,

Oppenheimer concluded. As information is obtained, and a given problem clarified, it may be appropriate to delete the item. Furthermore, newly developing problems, or ones demanding a fresh inquiry, may call for the addition of new items.

ness, established occupational deafness, and the elderly who exhibit a higher degree of hearing loss than the younger workers. Industry can benefit from their skills and still safeguard its risk by giving periodic hearing rechecks, he explained.

The regulation of hours of exposure to excessive noise, with provision for periods of recovery of the inner ear, the elimination of confined spaces, the use of ear protectors, the elimination of vibration in machinery are all important features of a program designed to eliminate occupational deafness, he said.

Workers' Compensation Plans . . .

Indicating a need for cooperation by management, labor, and compensation boards, an otologist suggests steps to meet the problem of occupational hearing loss. Reports from the United States, Canada, and Great Britain discuss workmen's compensation programs—benefits, costs, and recommendations for improvements.

Suggests Program Against Industrial Hearing Loss

A constructive approach to the problem of occupational deafness, Abraham I. Goldner, M.D., a Flushing, N. Y., otologist, said, will avert the needless sacrifice of hearing ability provided that full cooperation is given by management, labor, and compensation boards.

Goldner, chief of Flushing Hospital's audiological clinic, reported that metal, pneumatic tools, spinning and weaving, aviation, telephone, rail transportation, repair shops, and similar industries are apt to have a noise hazard.

The bulk of occupational deafness exists at a subclinical level and is generally discovered, he observed, by virtue of an accident, superimposed pathology, routine audiogram, or a concerted group drive to obtain compensation.

Full Cooperation

Industry, he stated, must recognize that a health problem exists. It is his belief that industry must co-

operate with and financially support the enterprises now seeking further information about occupational deafness. Labor should avoid adamant attitudes and seek adoption of measures based on scientific accuracy rather than economic expediency.

Administrators of workmen's compensation laws and legislators, he noted, should be receptive to methods of cushioning severe financial blows. He believes they should also support research designed to lessen the acoustic hazard and facilitate the accurate evaluation of hearing loss and the proper determination of its cause.

All must recognize, he said, the existence in the population at large of a vast reservoir of undetected and unsuspected hearing impairments of various degree and cause. Only a careful hearing examination, including the audiometric evaluation, will demonstrate this loss, he said.

In Goldner's opinion, audiometric examinations should be part of the preemployment physical examination. The preemployment audiogram will make possible the hiring of workers with damaged ear drums and middle ear diseases, conductive deaf-

Industrial Injuries Plan In Great Britain

In Great Britain, the worker's compensation for an industrial disablement is now based on the degree of loss of physical or mental faculty and not on loss of earnings.

Disablement assessment by medical rather than economic criteria and other features of Great Britain's insurance system covering industrial injuries, which replaced the national workmen's compensation procedures in 1948, were described by Arthur Massey, M.D., D.P.H., chief medical officer of the Ministry of Pensions and National Insurance, London, England.

Supplements Wages

Under the new plan, Massey reported, a beneficiary may get an industrial disability pension while earning as much as he can. It follows, he said, that the pensioner has no financial incentive to refrain from working at full capacity.

Three types of benefits—industrial injury, disablement, and death—are available to eligible claimants among the 20½ million employed persons covered by the Industrial Injuries Act, Massey reported. He described the system as follows:

An injury benefit is payable up to 26 weeks to a person incapacitated by an accident or an occupational

disease. A disablement benefit is payable if incapacity for work continues after the injury benefit stops.

The usual disability benefit rate ranges from 11 shillings a week for a 20-percent disablement to 55 shillings for a 100-percent disability. A lump sum payment is made to persons less than 20-percent disabled. Various supplements, such as an unemployability supplement and allowances for constant attendance, special hardship, and hospital treatment, may also be awarded.

First, the local insurance office, one of the approximate thousand located throughout the country, decides whether an accident has arisen out of and during the course of employment and, on the basis of a medical certificate, whether it has caused incapacity for work. Most disease cases are referred for diagnosis to a local examining medical practitioner.

After the local insurance officer has admitted the claim, general medical boards at more than 100 strategically located centers assess the degree of disablement or loss of faculty caused by the occupational accident or disease (with the exception of pneumoconiosis, byssinosis, and, tuberculosis).

Special Assessment

Tuberculosis, the first disease really common in the general population to be covered, is diagnosed by a chest specialist. Scheduled occupations consist mainly of medical treatment or nursing of tuberculosis patients, and ancillary hospital work, and research, laboratory work, or autopsies in connection with tuberculosis.

Pneumoconiosis and byssinosis are also considered separately, and the successful claimant proceeds direct to disablement benefit without antecedent injury benefit since the incapacity occurs in the late stages.

Special medical boards at nine main centers, accessible to such industries as mining, pottery, metal working, and cotton spinning, verify by clinical examination a preliminary pneumoconiosis or byssinosis

diagnosis and assess the amount of disability.

Pneumoconiosis is now compensated down to 1 percent of disablement. The limit before 1954 was 5 percent. In a recent development, a benefit may be allowed for pneumoconiosis contracted in an unscheduled dusty occupation.

Admission of byssinosis claims is predicated on two conditions: at least 20 years of employment in a scheduled occupation and permanent disablement amounting to 50 percent or more. Prior to 1948, a 100-percent disablement was required. Coverage, formerly applying only to raw cotton workers, has been extended to certain categories of waste cotton workers.

Diseases added to the schedule since 1948, in addition to tuberculosis, are beryllium poisoning; carcinoma of the mucous membrane of the nose or associated air sinuses and primary carcinoma of a bronchus or of a lung occurring in nickel workers; and papilloma of the bladder in certain chemical workers. There are now 39 occupational diseases on the schedule.

The industrial injuries fund is formed by weekly contributions from employers and insured persons. To this is added an exchequer payment at the annual rate of one-fifth of the sum of the combined contribution.

Rehabilitation Needs Link To Compensation Services

The most promising aspect of State workmen's compensation programs is rehabilitation, declared Jerome Pollack, B.S., program consultant, social security department, CIO-United Automobile Workers. However, he said, rehabilitation services are not included as part of workmen's compensation in most States, and they are not well coordinated with services provided under the workmen's compensation program.

It has been estimated that in the United States only 3 percent of the

workers injured on the job are receiving the types of services they need to rehabilitate them, Pollack stated.

According to Pollack, the extent of medical care programs is far greater than was anticipated when the workmen's compensation laws were written. Four out of five civilian employees are now entitled to medical care for work-connected injuries, he said, and the cost of the workmen's compensation program is about 3 percent of all private expenditures for medical service and about 17 percent of the amount paid by voluntary insurance plans. Care for occupational injuries is not provided by these plans, Pollack said, and as they become more comprehensive, greater coordination with workmen's compensation will be needed.

Under present workmen's compensation programs, the extent and amount of medical care are limited by statute in many States, and rehabilitation frequently is not possible within these limits, Pollack stated.

Early legislation did not stipulate the quality of medical care to be provided injured workers and often limited fees to the amount charged "in the same community for similar treatment of injured persons of a like standard of living." This criterion is subject to a variety of interpretations and does not always result in the best care for the patient, Pollack said. He stated that in all but nine States the employer or the insurance company designates the physician.

Rehabilitation Services

In most States, rehabilitation is not sufficiently coordinated with the Federal-State vocational rehabilitation programs, Pollack stated. Personnel and facilities are scarce, and patients must often travel long distances to reach the few rehabilitation facilities that are available. Also, he maintained, new incentives are needed to encourage interest in rehabilitation; most employees are not sure of its advantages and many

prefer a cash award or a permanent pension.

Pollack recommended that a study be made to determine how to assure workers of competent and impartial care. He suggested that minimum standards for handling medical care problems be established for insurance companies, State funds, and employers' medical departments, and that the function of the industrial board or commission in medical care be explored.

He also recommended that rehabilitation be made a benefit of workmen's compensation and available to all who need it.

Workmen's Benefits High, Employer's Costs Low

Ontario's 40-year experience with a workmen's compensation program has proved so satisfactory to employers, workmen, and the medical profession that it has been copied by every other Canadian Province.

Authors of this statement and of a description of the Canadian Province's program in relation to quality of medical care were B. H. G. Curry, M.D., chief medical officer of the Ontario Workmen's Compensation Board; J. E. F. Hastings, M.D., D.P.H., research fellow, and G. H. Hatcher, M.D., D.P.H., assistant professor, both of the University of Toronto School of Hygiene; and Mary A. Ross, M.A., Ph.D., medical statistician of the Ontario Department of Health.

Program Features

In addition to the exclusion of the law courts and private insurance companies from its administration, the plan features comprehensive medical care provided by private medical practitioners on a fee-for-service basis under the supervision of the three-member Ontario Workmen's Compensation Board, they reported. At present the board, appointed by the government, is composed of a former employer, a former

union representative, and a physician.

The board is the sole judicial and administrative authority for collecting premiums from employers, adjudicating and paying benefits to injured workmen and supervising complete medical care, including rehabilitation, they said.

The benefits were termed more generous and the costs to employers less, than in most American jurisdictions. This has been achieved without direct cost to the workmen or to the taxpayers, they said, since the complete costs are obtained by annual assessments from the employers.

In 1952, they reported, Ontario paid 75 percent of the employee's maximum earnings up to \$4,000 a year, or \$57.69 a week, for total disability from the first day of the accident, either as a lifetime pension or for the term of disability.

Since no money is spent on litigation or insurance company administrative costs and dividends, they pointed out, 89 cents of every \$1 paid for workmen's compensation is spent on payments or medical benefits to workmen.

Medical Care

Throughout the administration, they said, the pressure is on the injured workman and his employer to seek the medical care needed for an industrial illness or accident. It is the general policy to let the patient choose his own physician and to get remedial surgery in a general hospital.

The physician, the employer, and the employee each submits a notification of accident to the board. The physician also submits his accounts and details of care to the board and is paid on a fee-for-service schedule approximating the minimum recommended by the Provincial medical association.

The remuneration rate is high enough to keep the physician from being dissatisfied with care of compensation cases, they stated, and the

quality of his services is also governed by the knowledge that the diagnosis and treatment are reported to the board and may be reviewed by other competent physicians.

To augment this care, they reported, the board maintains wards in several hospitals where problem cases may be brought for assessment and a special 518-bed medical rehabilitation center, where physical medicine and work trials can be conducted.

Featured at the rehabilitation center, they reported, are conditions set up to simulate those of the workman's actual job, laying railroad track, for example. The patient must demonstrate that he is able to work a regular 6-hour day before he is discharged to full employment.

Outlines New Guidelines For Compensation System

A set of operating guidelines for a "modern workmen's compensation system" which the Subcommittee on Industrial Relations of the American College of Surgeons feels essential for the attainment of the basic principles for the rehabilitation of the disabled worker was outlined by Alexander P. Aitken, M.D., chairman of the group.

On the subcommittee, Aitken said, were representatives from labor, insurance carriers, public health and vocational rehabilitation agencies, and the medical profession. He said they unanimously agreed on the report, the product of 4 years of study.

Some of the proposals outlined by Aitken can be put into effect only by changes in administrative rules and in the compensation laws.

The rehabilitation problem, Aitken said, is one of many facets. Although it is of direct concern to the medical profession, he said, the failure of labor, management, insurance carriers, administrators of compen-

birth order were also put aside, as were those showing plural births. This left 42,277 births remaining for study, Rider and his co-workers reported. Of this total, 27,979 were white and 14,298 were nonwhite.

Results of Study

They found that 6.8 percent of the white infants born singly and alive were premature. The frequency varied from 7.3 percent in the lowest socioeconomic tenth of the city to 5.1 in the highest. The differences between economic strata became even more apparent, they said, when the figures were adjusted for maternal age and birth order. The ratios then ran from 5.0 percent at the highest level to 7.6 at the lowest. Neither adjusted nor unadjusted figures, Rider and his associates reported, showed much variation among the lower four brackets.

Incidence of Prematurity Higher at High Altitude

Studies of the effect of altitude upon birth weight have been prompted by the discovery that the incidence of premature babies (as determined by birth weight) for a high-altitude county in Colorado is three times the

State average. Thus far the findings are not conclusive, according to the report by John A. Lichty, M.D., Rosalind Y. Ting, M.D., M.P.H., Paul D. Bruns, M.D., and Elizabeth Dyar, Ph.D.

Dr. Lichty, Dr. Ting, and Dr. Bruns are, respectively, associate professor of pediatrics, pediatric research fellow, and associate professor of gynecology and obstetrics, University of Colorado Medical School; Dr. Dyar is professor of nutrition and dean, School of Home Economics, Colorado A & M College.

Local physicians, they noted, have stated that many of the babies born in this county (Lake County) are small but are not prematurely born. Supporting this idea is the fact that neonatal mortality was only about twice the State average for the same period, 1949 through 1953, they indicated.

To test the theory that high altitude accounts for the high incidence of premature, or small, babies in Lake County (altitude, 10,000 to 11,000 feet), comparisons of birth weights of babies born there with birth weights of babies born elsewhere were made. Some of the data are shown in the table.

In each weight group, Lichty and his associates specified, the Lake County babies were about three-

fourths of a pound smaller than babies born in Denver (altitude, 5,280 feet). The fact that the percentage distribution of weights for babies born in Cripple Creek, Colo. (altitude, 9,000 feet), is closer to the distribution for the Denver babies than to the distribution for Lake County babies, however, seems not to support the theory, they noted. But they considered the reliability of the Cripple Creek distribution questionable because of the small number of babies involved.

Race and Diet

Also investigated was the possibility that race is a factor in the high incidence of prematurity in Lake County, since about one-third of the county's population is "Spanish." Comparison of average birth weights of "Anglo" and "Spanish" infants in this county and in Denver revealed no significant difference between the two race groups, they stated. They suggested, however, that the factor of race be studied further.

Diet likewise seems not to be related to the prematurity situation, they indicated. A comparison of dietary intake of Lake County mothers of full-term babies with that of Lake County mothers of premature babies did not reveal any significant difference.

Percentage distribution of birth weights

Birth weight in grams	United States ¹ (percent)	Baltimore ² (percent)	Denver ³ (percent)	Cripple Creek, Colo. ⁴ (percent)	Lake County, Colo. ⁵ (percent)
1,000 or less	0.5	0.6	0.7	0.4	0.9
1,001-1,500	.6	.7	.8	1.6	3.3
1,501-2,000	1.4	1.8	1.9	5.3	13.7
2,001-2,500	4.9	5.8	8.3	10.6	30.4
2,501-3,000	18.1	23.3	27.4	31.4	32.2
3,001-3,500	37.7	39.4	40.8	39.6	17.2
3,501-4,000	27.1	21.8	16.7	9.0	2.4
4,001-4,500	7.7	5.5	3.0	2.0	-----
4,501 or over	2.1	1.1	.3	-----	-----

¹ Number of babies, 33,000.
² Number of babies, 9,523; altitude, sea level.
³ Number of babies, 10,566; altitude, 5,280 feet.
⁴ Number of babies, 244; altitude, 9,000 feet.
⁵ Number of babies, 577; altitude 10,000 to 11,000 feet.

Perinatal Mortality Rate Shows Areas of Need

The socioeconomic conditions of expectant mothers, their state of health, and the care they receive during pregnancy are, aside from obstetric services, the determining factors in death rates for infants during the first week of life and after 28 weeks of gestation, according to the implications of a study reported by three members of the New York City Department of Health. These periods of early life and late fetal existence are grouped under one classification—called perinatal—because similar conditions

may cause death at both stages, said Jean Pakter, M.D., chief, maternity and newborn division, Carl L. Erhardt, B.B.A., director, bureau of records and statistics, and Harold Jacobziner, M.D., assistant commissioner.

Recent years have seen marked progress in saving the lives of mothers and older infants, they reported, but the least improvement, shown by a comparatively slow decline in perinatal mortality rates, has been in bringing pregnancies to a successful conclusion. In New York City, where home deliveries are extremely rare, this is largely a hospital problem, they said.

The reported study analyzed New York City data for 1951 and 1952 to determine the perinatal death rates in individual hospitals and to discuss the factors, other than obstetric care, influencing the rates.

Hospital Population

Pakter, Erhardt, and Jacobziner believed that the race, age, and parity of the patients and the extent of their prenatal care, among other factors of hospital population, are constant influencing factors. Race, they said, is largely influential since it reflects socioeconomic status. Mortality rates in the three categories of hospitals studied were quoted to support their contention.

A tabulation showed that more than 180,000 deliveries occur annually in 103 city hospitals. Approximately two-thirds of the mothers in this area are under private care, they said. The mothers are delivered either at proprietary hospitals—privately owned business enterprises open only to patients who pay the full cost of their care—or at voluntary hospitals which are nonprofit institutions with varying numbers of paying and nonpaying patients. One-third of the mothers, the study found, are delivered either at municipal hospitals, which largely provide free care, or in the public wards of voluntary hospitals.

Infant death rates, fetal death ratios, and perinatal mortality rates

were found to be highest for municipal, lowest for proprietary, and median for the voluntary hospitals, they reported. The inference is clear, they said, that higher mortality rates are associated with hospitals caring for people of the lower socioeconomic groups.

Size and Location

Two other factors were investigated for their possible effect on infant and fetal mortality—the size and location of hospitals. But these components appear to influence the rates only insofar as they reflect the background of the patients, they reported. Large municipal hospitals which cared for a great number of nonwhite patients showed significantly higher death rates than other large hospitals in the same category whose patients were mostly white.

The study showed that the aggregate perinatal mortality rate was found to be highest in Manhattan borough and lowest in Queens. They related this finding to the fact that 45 percent of the women delivered in Manhattan are service or nonpaying cases whereas in Queens the proportion of service cases is only 20 percent.

A number of other investigators were quoted in support of the thesis that medical care is not the whole answer and indicated that a relationship exists between infant and fetal death rates and the dietary and other prenatal care received by mothers.

Hospital Care Index

Investigation is needed, they said, to determine the extent to which hospital perinatal mortality rates represent indexes of obstetric care. Any such evaluation, they continued, must allow for the extrinsic factors considered in this study. But even without this adjustment, they believe that the rates are the most useful means of focusing the attention of public health administrators on areas in need of assistance. For instance, they concluded, the New York City Department of Health intends to

study closely those hospitals in which the perinatal rates exceed the city mean for their own institutional category.

Proposes Plan to Speed Prematures to Centers

A simplified plan for speeding prematurely born infants from hospitals to regional premature centers was advanced by Edward H. Townsend, Jr., M.D., director of the Rochester Regional Premature Center of the Rochester, N.Y., General Hospital.

Townsend's proposal would cut at least half of the time it now takes to transport the premature infants to the center by shifting the burden of transport responsibility from the regional hospital service to the hospital of delivery.

The way Townsend sees it, the hospital of delivery would first call the premature service to see if the infant can be accommodated. Then, after approval, a nurse would take the baby in any available vehicle equipped with a Prager carrier or portable incubator that can operate from an automobile electrical system. Thus precious time, crucial in this stage, would be saved. Waiting for the ambulance to arrive from the premature center, as far as 100 miles away, would be avoided.

The mortality rate among premature infants is maximal during the first 24 hours of life (57 percent) and 87 percent of the deaths attributable to prematurity occur during the first week of life, Townsend asserted. Hence, prematures should be moved before intervening complications dominate the picture, he maintained. Small hospitals, unable to spare nurses for transportation services, would have to solve this problem under the new plan.

Another advantage of the plan is that the prematures could be transported regardless of the time of delivery instead of waiting as is done now for daytime ambulance services from the regional center.

The Rochester Regional Premature Center serves a 10-county area in upstate New York, Townsend said. It was built by private funds but is operated with the cooperation and assistance of the bureau of maternal and child health of the New York State Department of Health.

Premature centers, whether urban, suburban, or rural, have prime responsibilities to the region they serve, Townsend said. First is the actual care of the premature infant, but of equal importance are the study and research of the problems of prematurity and the continual demonstration of optimal premature care; a premature center should serve as a station from which and to which physicians and nurses may travel to observe, to teach, and to improve the care of the prematures in the region served.

Find Perinatal Deaths Equal Deaths to Age 40

In New York State in 1951 perinatal mortality, deaths occurring after the fifth month of pregnancy and before the second month after birth, equaled the number of deaths in the age group between 1 month and 1 day and the 40th birthday, according to Edward R. Schlesinger, M.D., associate director, division of medical services, and Norman C. Allaway, biostatistician, New York State Department of Health.

Fetal and newborn deaths are the major remaining mortality problem in the field of maternal and child health, they said. The trend toward concentration and narrowing of the problem of perinatal loss demonstrates the need for increased research and public health services for women who present a history of previous child loss, they asserted.

Comparison of the 1951 study with the study made in 1936 shows that relatively little progress has been made in reducing the rate of perinatal loss in the more vulnerable group of women, those who suffered

previous child loss, they reported. No improvement can be demonstrated in the most vulnerable group of all, women with a history of loss of three or more previous children, they added.

Women who experienced perinatal loss were 2.7 times more likely to suffer loss in subsequent pregnancies than women without such loss, according to the 1951 study. In 1936 this figure was only 2.2, Schlesinger and his co-workers said. The expectation of loss in later pregnancies (see chart) increases sharply with the number of previous losses, they reported.

Comparing the Studies

Comparison of the 1951 and 1936 studies showed the following:

The 1951 study included 106,344 births (fetal deaths and live births) as compared to 53,653 in 1936. In 1951, only 46 percent of the women had had only one previous child; in 1936, this figure was 38 percent. Only 7 percent of the 1951 group had had five or more children; in 1936, this figure was 18 percent. In 1951, 12 percent of the women had lost one previous child or more; in 1936, 24 percent had lost at least one child.

In 1951 mothers had a previous child loss rate of 68.0 per 1,000 total births; in 1936 the rate was 124.5. The fetal death rate was 16.6 per

1,000 total births as compared to the rate of 26.0 in 1936. Neonatal death rate in 1951 was 18.6 per 1,000 live births; in 1936 the rate was 30.4. The perinatal death rates in 1951 and 1936 were 34.9 and 55.6 per 1,000 total births.

In 1951, the perinatal death rates among children of mothers according to previous loss ranged from 29 among women with no previous loss to 253 among those with 4 or more previous losses. In 1936 the corresponding rates were 43 and 189.

Tests Value of Services For Colorado Prematures

How many and what kind of illnesses do premature infants have during their first year?

What are the differences in the kind and amount of preventive illness services received by premature infants with less than 4 illnesses and those with "many" (4 or more)?

Could any of these differences be utilized in preventing illnesses in these children?

The answers to these questions were the objectives of a study reported by Georgia B. Perkins, M.D., M.P.H., assistant professor of preventive medicine and public health, University of Colorado School of Medicine, and regional medical director, Region VIII, Children's Bureau.

The study was based on a sample group of 144 premature infants admitted to the Premature Infant Center of Colorado General Hospital.

Perkins reported the following findings:

Of the group, 124 were alive at discharge.

The number of illnesses of the premature infants followed for 1 year (86) varied inversely with the length of medical supervision.

Seventy-three percent of the infants had few illnesses, and 27 percent had many illnesses.

Sixty percent of the illnesses were infectious in origin, and 70 percent

Perinatal death rates by number of previous child losses in the 1936 and 1951 studies in New York.

of these were of the respiratory-pulmonary system.

Fifty-two percent of the hospitalized and 65 percent of the nonhospitalized illnesses were potentially preventable.

The routine child health conference, the pediatric clinic, and the emergency room shared equally in the care of these illnesses.

Babies weighing 1,001 to 1,500 grams at birth had fewer illnesses than those weighing more or less. This suggests the possibility of re-evaluating discharge criteria.

Babies kept in the hospital for 41 days, or more, after birth were less likely to have many illnesses than those kept 40 days or less.

Analysis of the time of public health nurse visits suggests the possibility that these visits help prevent illness.

The highest percentage of those having many illnesses had no medical social service. Analysis of medical social service suggests a definite and direct relationship to illness prevention.

They found little beriberi or other disabilities which could clearly be ascribed to a lack of thiamine. Unusually severe retinitis which produced marked and more or less irreversible lowering of visual power was apparently not due to thiamine deficiency alone. Further investigation of the condition, which, they said, could be the result of combined deficiency in the type of diet described, was recommended.

Vicious Circle

Rake and Yang believe that chronic undernutrition and vitamin deficiency predispose to chronic parasitism, all other things being equal. Certainly, they continued, parasitism predisposes to increased malnutrition. Hookworm infestation, for example, was as high as 34 percent among the Marines at Tsoying, where some of the nutritional studies were carried out. Anemia was prevalent in some units, they reported. In some cases it was macrocytic in character and probably due to the marked deficiency of B₁₂ and partial deficiency of folic acid. However, they said, hookworm infestation is undoubtedly also responsible. Most, if not all, the patients who had severe anemia harbored hookworms.

Recommendations

Measures suggested by Rake and Yang for the improvement of general health conditions included an attempt to eliminate the intestinal worms by the use of a polyvalent vermifuge. Addition to the diet of deficient vitamins and other nutrients was also recommended.

Canada Reports Nationwide Height-Weight Survey

For the first time in Canada, individual heights and weights can be compared with a true national average, according to L. Bradley Pett, M.D., Ph.D., chief of the nutrition division, Department of National Health and Welfare, Canada.

Health in Foreign Countries . . .

From Canada, Formosa, England, and Australia come reports concerning problems and programs in a variety of health and related fields: relationship of weight to health, nutrition, laboratory and radiological services, rehabilitation of derelict families, social-medical research, and zoonoses.

Show Vitamins Lacking In Ample Rice Diet

Chinese National Army troops stationed in Formosa received an abundance of calories from a predominantly rice diet, but were afflicted with vitamin deficiency disease that ranged from severe to mild, according to a study conducted in the spring of 1954.

Geoffrey W. Rake, M.B., and Wentah Yang, M.D., respectively, research professor of microbiology in the department of medicine at the University of Pennsylvania and the deputy surgeon general of the Chinese National Army, said that parasitism was prevalent, but often in a relatively symptomless form.

The basic ration of cereal, soybeans, and oil was uniform for all troops, they said, but a system of local purchase caused the type and

even the amount of animal protein and vegetables to vary among different units. In general, the diets were markedly deficient in fat, B₂, and calcium, and somewhat deficient in niacin and ascorbic acid. The principal vitamin deficiencies in the diet, they reported, were in riboflavin, vitamin A, and niacin.

Unexpected Finding

Rake and Yang said that there was surprisingly little evidence of disability produced by ascorbic acid deficiency. They suggested that pyorrhea, very prevalent among the troops, might conceal lesser effects of this deficiency on the gums. The possibility that pyorrhea may itself be an indication of vitamin C (ascorbic acid) deficiency is more interesting, they continued, and said that this was observed in Denmark after World War II.

Tables, believed to be the first of their kind obtained by statistical sampling of the heights and weights of an entire population, have been compiled and will be available from the Department of National Health and Welfare.

"Weight relationships to health are among the most fundamental problems needing study at the present time," Pett said, and these data should provide a sounder basis than has been available heretofore for studying the effects of weight in aging and in the degenerative diseases.

Using the area stratification method, the Canadian study obtained height, weight, and age data for 22,000 Canadians in 1953. Remote areas as well as heavily populated regions are represented in the random sample.

Overweight is not the same thing as obesity or adiposity, Pett con-

tinued. Lack of clear definitions has resulted in actual misuse of these words, and when it becomes possible to differentiate these terms, greater understanding of the importance of diet and greater success in controlling degenerative diseases may result, he stated.

Muscular hypertrophy may result in increased weight, Pett said, whereas a moderate accumulation of fat may not do so, and therefore, in defining obesity or adiposity, it becomes important to have some measure of body fatness or leanness in addition to weight and height measurements. For this reason, in the Canadian weight-height survey, a skinfold measurement on the back of the upper arm was included in the data.

Height-Weight Increases

The height-weight averages in the Canadian survey confirm the belief

that in the last 30 years children have been taller and heavier at a given age than their parents were at the same age. However, only the rate at which height is reached has increased; adult weights have not changed a great deal.

Although weights and heights have shown a progressive increase during the past 30 years, the rate of increase has been slower in the last 14 years than in the preceding 16 years. The reasons for this slower rate of increase are not clear, Pett said, but he suggested that several factors may explain it. One of these may be more widespread nutrition education, with greater emphasis on the general effects of a balanced diet than on growth rates.

"I would like to believe that this factor is operating in this slowing down of the averages, because I believe it is the correct approach to a longer and fuller life," Pett stated.

Canadian heights and weights for age.

"Rapid growth may be one of the factors in our increase in degenerative diseases."

Average weight for adults drops at ages 45-54, climbs again, and then drops, the speaker concluded, and these changes may indicate some fundamental aspects that have not yet been studied. (See chart.)

Explains Canadian Grants For X-ray Services

As one means of providing better diagnostic services in Canada, the Canadian Government in 1953 established a laboratory and radiological services grant, reported F. W. Jackson, M.D., director of health insurance studies, Department of National Health and Welfare, Ottawa.

The purpose of the grant is to assist the Provinces in providing laboratory and X-ray diagnostic services, purchasing equipment, training personnel, and conducting surveys and studies. The amount of the grant, to be matched by each Province, is 30 cents per capita the first year, increasing by 5 cents each year to a maximum of 50 cents per capita.

Jackson defined laboratory and X-ray diagnostic services as "those procedures which are ordinarily requested by a registered medical practitioner and performed by workers employed in institutions approved by the Provincial authority for the purpose of assisting the physician to diagnose the presence, absence, or status of disease, defect, or disability."

The grant will make more and better diagnostic services available throughout the Provinces, Jackson said, and will save time and money for the patients because the services will be available close to their homes.

Physician's Role

Services financed by grant funds must be provided to the public at not more than cost, Jackson said. He stressed the fact that the traditional physician-patient relationship is to be maintained and said that there

has been no thought of regimenting or centralizing personal health services. Rather, the objective is to strengthen the physician's hand and thus to bring greater and more direct assistance to the people themselves.

Jackson reported that the Manitoba Deputy Minister of Health had stated that in that Province the laboratory and radiological services grant had proved to be an inducement to the young and modern medical practitioner to practice in rural areas, had raised standards of service in rural hospitals, and had made the advantages of modern scientific diagnostic services accessible at reasonable cost.

New Approach Might Aid English Problem Family

Recruitment of experienced area rehabilitation officers to supplement the practice of using health visitors and other academic social workers was strongly advocated by a British health officer as a possible way of coping with the problem of derelict families.

H. C. Maurice Williams, Dr.P.H., the medical officer of health for Southampton, England, said that despite the education, housing, and income available to the working class family today, England still has the problem of "submerged families." These families, with histories of ignorance, poverty, and vice, number an average 2.98 per 1,000 families.

"It is little wonder that when a family has to perform every function of life within the confines of a room 14 feet by 12 feet they degenerate," he remarked.

The Misfit Groups

Socially misfit families can be broadly divided into three groups, according to Williams, even though there is no well-defined common yardstick of measurement.

One group shows affection for the children. These children are supplied with sufficient but unsuitable

food. The mother has many pregnancies and is completely unable to cope with the routine work of domestic life. The father fails to encourage his wife. His laziness and long record of unemployment, Williams felt, does not disturb him so long as he can receive from public assistance arrangements almost as much money as he would if he went to work. If caught in the early stages of degeneration, this group is capable of rehabilitation, Williams stated.

The father and mother in the second group, although usually educated above their station, have a low moral sense and no concern for their children's welfare or their legitimacy. Living conditions are satisfactory for the third group, but these parents are the ones who subject their children to physical cruelty. Fortunately, they are in the minority.

"The only satisfactory method of dealing with so-called problem families is as a family unit," Williams stated. The area rehabilitation officers he recommends for preventing family deterioration would be men and women experienced in life, who would mix intimately with the people of a locality, visit the public houses, and while there, in conversation and gossip, ascertain the potential families who are rapidly going downhill. The health visitor should come into the picture when the family has been returned to some degree of normality and when they are receptive to advice and health education, he added.

Other Solutions

Two other approaches of working with the problem family as a family unit were described by Williams. In Southampton, a few derelict families were selected to see whether the altering of their circumstances would help them change their standard of living. Constant visitation and advice, the promise or provision of rehousing, and help toward getting furniture have proved to be some excellent means of bringing about rehabilitation. Although this method

at first sight appears fairly costly, it is far cheaper than leaving the problem untackled, he commented.

The Mayflower Home operated by the Salvation Army in Plymouth, England, is a pioneer experiment. Commitment to the home is offered as an alternative to prison sentence. Mothers live there with their children and may be visited by their husbands. The prevailing assumption is that a wholesome, nourished body is more responsive to spiritual correction than an unclean and unfed one. The first lesson begins in the bathroom. Then the women are taught simple rules of housewifery and the importance of adhering to a methodical, daily routine. On completion of their daily tasks, they are free to visit the local cinemas and teashops.

The schools should pay more attention to the teaching of housewifery and domestic responsibilities, Williams believes. Children of problem families could be selected for additional instruction and the curriculum adjusted to this end.

Infant Mortality Pattern Noted in English Study

A rise in postneonatal mortality with the mother's parity has been noted in a current study in England.

Reporting this and other studies of the social medicine research unit, Medical Research Council, London, was J. N. Morris, D.P.H., director of the unit.

This rise, Morris specified, occurs in each age group, but it is sharper among younger women. The trend is evident in the different social classes, indicating that it is not simply a matter of young mothers with large families being more common among the poorer classes, he added.

Analysis by cause of death shows that the pattern is accounted for by the deaths from "environmental" causes—infections and accidents, he stated.

This study, a joint inquiry with

the General Register Office, is concerned with the 1½ million births in 1949 and 1950 in England and Wales and the 80 thousand stillbirths and infant deaths among them. It is mainly a theoretical exercise in social biology, Morris explained, but he said that immediately practical results may also emerge. For example, it may be of value in the identification of "vulnerable" groups requiring particular attention from public health services.

Duodenal Ulcer

From a study of the family situation of 32 men aged 16 to 25 years who have duodenal ulcer, Morris reported the following: Mothers of these men tend to be dominant in the home; to have overprotected, overrestricted, and overindulged their sons; and to have an unusually great amount of psychosomatic disorder.

The objective of this study, he noted, is to try to identify patterns of family relations and of child upbringing which may be connected with the development of ulcer. In his opinion, one of the greatest needs in social-medical research today is to develop working partnerships with the social sciences and psychiatry.

Another study is trying to learn what is happening in the field of general practice. Essentially an essay in method, this study has found, Morris reported, that the general practitioner spends almost one-half his time dealing with serious, mostly chronic, disease. It has also found that about 13 percent of all their work is concerned with bronchitis, he said, a finding of interest in connection with the increased attention in the United Kingdom to respiratory disorders and atmospheric pollution.

Outlines Control Measures For Australian Zoonoses

Hydatid disease, Q fever, brucellosis, leptospirosis, psittacosis, and arthropod-borne encephalitis are the

important zoonoses in Australia. The fact that hydatid disease is still a problem—affecting 40 percent of farm and sheep station dogs—indicates its continued importance in public health, said A. R. Southwood, M.D., director general of public health for South Australia.

Southwood based his information on reports given to the 1953 Australasian Science Congress and on his observations as a member of the Australian National Health and Medical Research Council.

Effective cooperation of veterinarians, entomologists and other zoologists, epidemiologists, laboratory experts, and practicing physicians is necessary to prevent epizootics, he said. In the field of zoonoses, more than in any branch of medicine, it is necessary to study the ecology of the animal, the pathogen, the vector, and man, he continued.

Hydatidosis

Wider use of educational methods was urged by Southwood for the control of hydatid disease rather than attempting to police laws, such as those restricting the number of dogs.

Hydatid disease is responsible for about 50 deaths a year among Australia's 8 million people, he stated. The amount of illness it causes is hard to estimate, but for a disease so easily controlled, any amount is too much, he noted.

The country has patterned its control program on Iceland's campaign of public education, better control of slaughtering, and veterinary inspection of all meat. Control measures also include the anthelmintic treatment of dogs once a year. Arecoline hydrobromide, properly used, clears dogs of infestation, but no drug treatment is effective against the hydatid cysts, Southwood said. Surgery may be resorted to when the disease occurs in humans.

Other Zoonoses

In discussing control measures for the leading zoonoses, he said:

Many of the zoonoses have a typical occupational bias and are manifested in man by vague illnesses and little fevers, making accurate diagnosis difficult. Human sufferers respond well to some of the antibiotics. Q fever patients are effectively treated with chloramphenicol or aureomycin. In treating psittacosis, aureomycin or terramycin is preferred to penicillin, although large doses of penicillin are efficacious. Aureomycin arrests undulant fever attack, but relapses are common.

Q fever in man probably occurs more often by inhalation of dust from hides which carry dried feces of the infected cattle ticks than through skin contact with infected beef. Preventive measures include control of the common animal reservoirs, of air contamination, milk supplies, and of

exposed individuals by means of protective clothing, respirators, immunization.

The spread of brucellosis would be stopped by the vaccination of all young cattle, sheep, goats, or swine, the elimination of all infected animals, and the pasteurization of all milk supplies.

Leptospirosis should be controlled by the destruction of rats; the elimination or treatment of infected pigs and dogs; the control of moist conditions favorable to leptospirae, including the proper drainage of canefields, cowyards, and piggeries. Since the organisms can survive in mud and water, people should wear protective clothing, such as waterproof boots, overalls, and gloves, and avoid swimming in infected water.

cedures were broken down into the referral standards of their separate component parts: The Snellen component of the Massachusetts test was compared with Snellen testing by the Oregon teachers and by trained test consultants. Conclusions drawn from the study were based on 3,775 Massachusetts tests, 3,104 reports of teacher findings, and 365 similar Snellen-observations made by an experienced operator testing the control group. Some of the findings were:

The Massachusetts test is an effective case-finding method, justifying 75 percent of its referrals. It disclosed more than twice as many probable defects of vision as were found on teacher screening. Its highest efficiency lies in the Snellen component, which yields 61 percent of all failures and is confirmed by professional examination in 84 percent of the cases referred. The plus lens and Maddox rod components are less selective, but provide a battery of tests whereby the more elusive visual defects may be brought to examination. Approximately 66 percent of these will require care in the combined judgment of physicians and optometrists.

The Snellen-observations made by the trained operator disclosed the same percentage (16.7) of probable defects among the children as did all parts of the Massachusetts test (16.6), indicating close correspondence in the case-finding potential of the two methods when given by experienced operators.

Screening by the Snellen test plus teacher observation is not to be disparaged as a case-finding method, but it has not reached its full potential in the Oregon schools. Only rarely were teacher observations recorded on the school health records, so that the failures in the teacher-screened group were essentially Snellen test failures—thus, only comparable to failures to pass the Snellen component of the Massachusetts test.

Still to be investigated is how large a percentage of cases referred

Vision and Hearing Testing . . .

How effective the Massachusetts vision test is in identifying school children who need visual care and how the test compares with one State's school vision screening procedure can be determined from the Danbury and Oregon studies. Also discussed is the first attempt at citywide testing of preschool youngsters for hearing.

Oregon Compares Snellen And Massachusetts Tests

Will the Massachusetts vision test disclose more or fewer vision defects than are found by the practice, current in Oregon, of having teachers give the standard Snellen test and report observed signs of poor vision?

If a trained test operator gives the Snellen test and makes similar observations, how will the defects found compare with those disclosed by the Massachusetts test?

Will the probable defects uncovered as a result of any one of these

three procedures justify referral, in terms of correction or care recommended on professional eye examination?

These basic questions were posed as the objectives of a study of vision screening made in 1953-54 by the Oregon State Board of Health and reported by Eleanor B. Gutman, M.D., M.P.H., director of the board's vision conservation section.

Gutman pointed out that continued controversy over school vision screening stimulated comparison of Oregon procedure with the widely used Massachusetts test. For comparative purposes, both testing pro-

for examination on observed signs and symptoms alone will warrant treatment for specific defects.

Hearing of Preschoolers Tested in Buffalo

As a byproduct of summertime availability of 3 full-time audiometric technicians, a preschool hearing screening program was launched 4 years ago in Buffalo and rural Erie County, N. Y. Since then, 125 hearing clinics have been held in conjunction with topical fluoride clinics for preschoolers, at testing sessions in the schools on registration day, and at well-publicized special clinics.

In describing this first attempt at mass testing very young children with a pure tone audiometer, Buffalo's deputy health commissioner, William E. Mosher, M.D., M.P.H., and Adfur E. Maines, M.D., director, school health service, said delaying the initial screening of children until the second grade can no longer be justified.

The Buffalo school schedule now calls for testing youngsters on entering kindergarten or first grade. This procedure has the advantage of early detection of hearing impairment and outweighs the possible limitation of individual screening tests in the older age groups.

The techniques used in Buffalo have proved effective, practical, and relatively inexpensive, Mosher and Maines asserted. The only major expense has been the salaries of the trained technicians. In their hands, the tests can be performed with sufficient accuracy to isolate a significant percentage of hearing losses among the test group. Repeat threshold tests under ideal conditions at the Buffalo Speech and Hearing Center have compared very favorably with the results of the field tests.

If a daily clinic attendance of 35 children could be maintained, it should be possible to test about 1,200 children in a 7-week period, the health officials believe. This esti-

mate takes into consideration the time devoted to the uncooperative child as well as the time-consuming threshold tests.

Screening Techniques

More than 5,000 children, 90 percent of them under 6 years and some

as young as 2, have so far been given the individual pure tone sweep test at speech range frequencies. Because of the high noise level in many of the testing rooms and the difficulty of getting young children to cooperate the 20-decibel hearing level was used. When a child failed to hear

Recent Advances in Rabies Control

When two dogs attacked a group of children going home from school last June, some of the children were bitten severely on the head and neck. Others suffered minor cuts and bruises. One dog had to be shot through the head. The other was taken into custody.

This attack started an imaginary rabies outbreak in the Republic of Neutralia, an imaginary country. The topic opened a panel discussion on rabies control at the 1954 Conference of Public Health Veterinarians.

On the basis of this hypothetical situation, the members of the panel outlined a control program and described in detail the steps necessary for the diagnosis of rabies in a biting animal, such as a period of observation, laboratory examination of the head for Negri bodies, mouse inoculation test.

Attention then turned to control measures, of which the most important, they agreed, is the vaccination of at least 70 percent of the dog population.

Next, the problem of wildlife rabies was considered. The reduction of species known to be particularly likely to spread the disease, such as foxes, was recommended, and the need for further study of rabies in wild animals was emphasized. Rabies in bats, recently given much publicity, was described as deserving additional investigation.

The discussion concluded with a brief report of results in the treatment of humans with rabies antiserum and a preliminary statement about the use of chick embryo adapted live virus for the prophylactic vaccination of man.

Hilary Koprowski, M.D., was panel moderator. He is assistant director of viral and rickettsial research for Lederle Laboratories, Pearl River, N. Y. The speakers were:

Ernest S. Tierkel, D.V.M., director, rabies control activities, Public Health Service, Atlanta; Donald J. Dean, D.V.M., veterinary consultant, New York State Department of Health; Leland E. Starr, D.V.M., public health veterinarian, Georgia Department of Public Health.

Also: John P. Fox, M.D., professor of epidemiology, Tulane University School of Medicine, and T. F. Sellers, M.D., director, Georgia Health Department.

2 or more of the test frequencies in either 1 or both ears at that level, and this was confirmed by a full threshold acuity test, he was considered a verified hearing loss and referred to a family physician, private otologist, or to a hospital hearing clinic.

Sixty-three children (1.2 percent) were found to have a verified hearing loss. Medical and educational recommendations were made for 44 children; 2 were recommended for further observation; and 7 were reported to have normal findings. Conductive deafness was the diagnosis in 30 cases, and nerve deafness in 2. Other causes of hearing loss included allergy, wax, and foreign body in ear canal. The most common recommendation was removal of tonsils and adenoids. With the exception of 1 deaf mute, hearing loss was not suspected by the parents.

In 1954, an effort was made to recheck all children found to have a verified hearing loss during the earlier clinics. The majority were found still to have a significant impairment at the time of the recheck audiogram.

Describes Danbury Study Of Massachusetts Test

How effective is the Massachusetts vision test in identifying the children whom ophthalmologists and optometrists find to need visual care?

Like any other screening process, vision testing has inherent errors of under-referral and over-referral, said Hollis M. Leverett, vision consultant, American Optical Company, Southbridge, Mass.

Although it is expected that some children who need attention may not be identified by screening and that others who do not need care may be referred for professional examination, reasonable efforts should be made to minimize these errors, Leverett stated. In his opinion, the criteria for referral and the adequacy

of testing in the schools are crucial factors.

Leverett, who guided the design of a new experimental model of the Massachusetts vision test, conducted the Danbury, Conn., school vision screening. This study is part of a broader program to evaluate the test and to improve the efficiency of the instrument and the test routine in the schools.

Each child was tested carefully. Those who failed were given a second opportunity to take the test. On the assumption that the children who could pass the second test would have constituted errors of over-referral, the retest procedure has obvious and crucial value, he remarked.

After describing standards for failure, which varied with the grade, procedures of referral for children not wearing glasses, and how recommendations were obtained from doctors for children wearing glasses, he summarized the results of the study:

For children tested through the glasses worn, it was found that 56 percent failed the first test and 45 percent failed both tests on retesting.

For children who did not have glasses, it was found that 20 percent failed the test and 12 percent failed both test and retest.

With or Without Glasses

Leverett said that the evidence presented makes it clear that the test performance of school children is subject to considerable variation. Eleven percent of the children wearing glasses and 9 percent of the children who do not have glasses change performance from fail to pass on retest.

Test results for children wearing glasses and for children not wearing glasses indicated marked differences in performance, chiefly, in test failure rate, rate of change from fail to pass on retest, and variations of failure rate with grade. Because of these variations, he believes it undesirable to apply the usual testing and referral practices to both groups.

Despite improved vision made possible by lenses, a large proportion of children wearing glasses were unable to meet the screening test standards, he stated. About 45 percent failed both test and retest.

Leverett considered the failure rate for children wearing glasses not surprising. Some have deficiencies which cannot be corrected to the level of test requirements. Others have deficiencies such that correction to that level is not desirable.

Inquiries were made to determine the visual care status of the children who were wearing glasses, Leverett reported. The doctors' reports indicated that, following the inquiries, 88 percent of the group had been examined within a 2-year period. A reexamination was considered desirable for 43 percent. Only 29 percent arranged reexamination as a result of the inquiries made.

It was Leverett's impression that, with slight modification, the inquiry procedure could be made exceedingly effective in encouraging the desirable periodic examinations for children who are under professional care.

Leverett said that the children not wearing glasses who failed the test were referred for a complete visual examination. The doctors' reports on these referrals indicated that:

For 72 percent, visual care was needed and prescribed.

For 23 percent, professional attention was indicated although visual care was not prescribed.

For 5 percent, no visual deficiency was identified.

Leverett noted that the criterion adopted to designate a "correct" referral would make a difference in the statistics.

If the immediate need for visual care were adopted as the criterion, 72 percent of the referrals were correct and 28 percent in error, he said.

But if the need for visual care or the doctor's opinion on the need for professional attention were the criterion adopted, 95 percent of the referrals were correct and only 5 percent in error, he said.

Deaths

per 1,000 population

Births

per 1,000 population

United States Vital Statistics, 1953-54

A new high for births and a new low for deaths appear very likely for 1954. Thus, the natural increase in the population of the United States—that is, births minus deaths—should be greater than for any previous year. Marriages in 1954 continued the decline which has been almost continuous since 1946. Divorces, which decreased sharply in the early postwar years, appear to be leveling off. These statements are based on provisional figures for States shown in the *Monthly Vital Statistics Report* for January–October 1954. Each month the figures are sent by State and local officials to the National Office of Vital Statistics, where they are used to obtain United States estimates.

Births

During the first 10 months of 1954, an estimated 3,344,000 births were registered, exceeding the number in these months of 1953 by 2.5 percent. If this lead is maintained for the rest of the year, about 4.0 million births will be registered, making 1954 the fourth successive

record-breaking year. Including unregistered births, the total will be 4.1 million.

In each year since the end of World War II, births have been at a considerably higher level than during the war or the immediately preceding years. Rising sharply after demobilization, the birth total (adjusted for under-registration) climbed from 2,858,000 in 1945 to a peak of 3,817,000 in 1947. It dipped slightly in 1948 and leveled off during the next 2 years. In 1951 the number of births again increased, and continued to rise in 1952, 1953, and the first 10 months of 1954.

The birth rate per 1,000 population in 1953 was 25.1, and, according to present indications, will increase slightly—to 25.2—in 1954. The latter figure is the second highest in 28 years, and is only 5.3 percent below the postwar peak (26.6) in 1947. In 1940, by comparison, it was 19.4, and during the depression of the 1930's, it had dropped to 18.4.

Much of the increase in births in 1953 and 1954 can probably be attributed to a continuing rise in the number of third, fourth, and fifth children. Data on birth order for these years are not yet available, but it is not expected that they will show an increase in the number of first births because of falling marriage rates since 1951.

Prepared by the National Office of Vital Statistics, Public Health Service.

Infant Deaths

per 1,000 live births

The seasonal variation in the birth rate during 1953 and in the first 10 months of 1954 was quite marked and closely resembled the pattern in previous postwar years. The rates for the first 3 months of 1953 formed a minor peak. This was followed by a sharp drop in April to the year's low of 22.0. In the next few months, the rate rose to a high of 26.7 (in August) before declining again. In past years, the birth rate has generally dropped at the end of the year. However, between November and December 1953, there was a rise of 2.5 percent. These measures are not adjusted for under-registration because of the negligible effect of this factor on changes from month to month.

Deaths

During the past 5 years, 1949-53, the death rate has remained nearly stationary, varying only between 9.6 and 9.7 per 1,000 population. This pattern will be changed in 1954, judging from the unusually favorable mortality experience of the first 10 months. For the period January through October, the death rate (on an annual basis) was 9.1 for 1954, compared with the previous low of 9.6 recorded for 1950, 1951, 1952, and 1953. Unless mortality for the remaining 2 months should be unexpectedly high, the death rate for 1954 will be either 9.2 or 9.3.

The infant mortality rate (the number of deaths under 1 year per 1,000 live births) promises to be lower in 1954 than the year before, continuing the general downward trend. This rate

Marriages

per 1,000 population

for January-October was 26.6 in 1954, compared with the previous low of 27.9 in 1953.

The outstanding feature of the year 1954 was the absence of any reported outbreak of influenza. In each of the previous 4 years, there was an outbreak of influenza in the early part of the year. The most severe was in January and February of 1953, and the accompanying chart shows the very large number of deaths resulting from the widespread occurrence of influenza and other acute respiratory infections. The year 1954 was the first since 1949 in which no outbreak occurred, and as a consequence the death rates for the chronic cardiovascular diseases, as well as for influenza and pneumonia, have been relatively low.

Marriages

During the first 10 months of 1954, fewer marriages were reported than in the same period of 1953, and the marriage rate declined from 9.7 to 9.2 per 1,000 population. In previous years, the estimated marriage rates for the January-October period, based on provisional figures, have not varied greatly from the rates for the entire year, based on final returns.

The decline in marriages may in part be attributed to the low birth rates of the 1930 decade, with the result that there are fewer young people of marriageable age in the present decade.

Monthly estimates of marriages in the United States are based on figures on marriage licenses, intentions of marriage, and marriages by reporting month, available from the individual

¹ Based on a 50-percent sample.

NOTE: Deaths are exclusive of fetal deaths and of deaths among armed forces overseas. Data are final for 1952, and are estimated for 1953 and 1954. Birth, death, and marriage rates are per 1,000 population excluding armed forces overseas; infant mortality rates are per 1,000 live births and are adjusted for the changing numbers of births. All rates are on an annual basis. Population figures were furnished by the Bureau of the Census.

States. The estimating procedure is described in the January 1954 issue (vol. 3, No. 1) of the *Monthly Vital Statistics Report*.

Divorces

Figures on divorces available on a current basis from 25 areas show that the numbers of divorces in the first 9 months of 1954 are lag-

ging about 4 percent behind comparable totals for 1953. For 21 areas, the 1953 total was almost identical with that for 1952. During 1952, the estimated number of divorces and annulments in the United States was 392,000, and the rate was 2.5. This is in marked contrast to 1946, when divorces were estimated at 610,000 with a rate of 4.3 divorces per 1,000 persons, the largest number and rate for any year on record.

PHR

Physical Activity And Arteriosclerotic Heart Disease

By PERCY STOCKS, M.D., D.P.H.

A POSSIBLE association between locomotory habits and arteriosclerotic heart disease has been suggested by results of studies of death rates in recent years, according to occupation, for coronary disease and for myocardial disease. Also, a rise in death rates for arteriosclerotic heart disease has accompanied an increasing use of the motorcar and has been noted particularly among those classes of men who use motorcars most and tend to walk least. I would suggest that statistical studies be planned in several countries aimed at obtaining more evidence to prove or disprove the hypothesis that lack of exercise may encourage the onset of coronary occlusion.

Recent research suggests that lipoid metabolism may be concerned in the etiology of atheroma. However, when atheroma is lethal it is usually because occlusion supervenes—and the determining factors for occlusion may have little to do with diet. It is not unreasonable to suppose that when the coronary arteries are

Statistical studies are needed to investigate the possibility, suggested by mortality figures for various occupations in England and Wales, that physical activity tends to protect the middle-aged from acute coronary occlusion.

atheromatous, it is the mechanics of the circulation rather than the chemistry of the blood which decides whether obstruction occurs in a large branch with resulting coronary crisis or in peripheral branches with more gradual myocardial degeneration as the outcome.

It has been observed that among men whose social conditions were most favorable, degenerative heart disease tended to express itself as coronary disease or angina pectoris, whereas at the other end of the social scale, where occupations involving hard physical work predominated, heart disease tended to take forms described on death certificates as myocardial degeneration (1). In 1951 I pointed out (2) that, although one-seventh of the 4,000 deaths attributed to coronary and myocardial diseases among navvies, coal hewers, dock laborers, and agricultural laborers were certified as due to coronary disease or a synonym of it, that proportion became greater with decreasing physical activity in the occupation. For example, the proportion of coronary to total myocardial and coronary disease was about one-quarter for metal machinists, printers, retail salesmen, sorters, and farmers, and nearly two-fifths for teachers, clerks, bankers, and administrative officials.

Morris and his associates (3) have now followed this up with a more detailed statistical study of the deaths in 1930–32 among 2½ million men aged 45–64 in social classes III to V, which comprise the skilled artisans, partly skilled workers, and unskilled workers. The occupations were classified into three groups, designated as physically heavy, physically light, and intermediate or doubtful jobs

Dr. Stocks is a senior research fellow with the British Empire Cancer Campaign. From 1933 through 1950, he was chief medical statistician, General Register Office, London, and in the years 1947–51 he served with the World Health Organization in the preparation of its Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death.

This paper was presented before a session on arteriosclerosis and cardiac diseases at the International Congress of Clinical Pathology in Washington, D. C., September 7, 1954.

within each social class. At each age period, 45-54 and 55-64, the coronary disease death rate was about twice as great for persons in physically light occupations as for those in the heavy occupations. For death rates from valvular, myocardial, and cerebral vascular lesions and arteriosclerosis without heart affection, no differences of importance were found between the physical activity groups. The same investigators also found from a careful study of early mortality rates from coronary disease during 1949-52 among bus conductors, bus drivers, postmen, and telephone operators working in the same areas of London that the death rate was lower among conductors than among drivers and lower among postmen than among telephonists. All this lent support to the hypothesis that in middle age physical activity tends in some way to protect the individual against coronary occlusion in an acute form.

Deaths Among Amputees

In 1951, an Advisory Committee on Cardiovascular Disorders and Mortality Rates in Amputees, appointed by the Ministry of Pensions in London, prepared an interim report on a statistical analysis of the subsequent histories of men who had lost one or more limbs in World War I.

In that study, for the 5 years 1945-49, the causes of death of a representative sample of more than a thousand men who had suffered a single lower limb amputation during World War I were compared with a control group of corresponding age distribution who had suffered from wounds without an amputation. The deaths attributed to coronary and myocardial disease combined formed practically the same percentage of all deaths in the two groups, but the ratio of coronary disease to myocardial disease within the combined total was higher among the amputees than among the controls. Although this was not generally accepted by the committee as having any significance, my personal opinion, expressed in an appendix to the report, was that there was probably a connection between these ratios and

the restricted physical activity of amputees. The recent work of Morris and his co-workers (3) has not caused me to change that opinion.

It has been suggested that the long-continued physical and emotional stresses and privations such as were experienced in the First World War both by men in the services and by civilians might have been a factor in the subsequent increase in coronary disease mortality; but such an idea is not incompatible with a favorable effect of regular physical exercise which involves no nervous stress.

Deaths Among Athletes

A recent paper by Rook (4) gives the result of comparing the mortality experience of 772 Cambridge University students who had taken an active part in sports while at the university with that of 710 men who had not done so. No evidence emerged that the sportsmen died at an earlier age than the control group; in fact, if allowance is made for their rather higher proportion of deaths from violent causes, the reverse must have been the case with respect to death from natural causes. Out of 387 deaths from nonviolent causes at ages under 65, when the certified cause of death was known, 9.3 percent of the sportsmen were said to have died of a cardiovascular condition compared with 12.1 percent of 289 in the control group. Because many of the deaths occurred before 1920, no more precise division of the heart conditions could be made; but at least this finding is not incompatible with the hypothesis.

Gonorrhea Detection by Urine Examination

By S. ROSS TAGGART, M.D.

AN INTENSIVE epidemiological and public educational program directed toward gonorrhea control has been disappointing because it has not been successful in rapidly reducing the number of cases of gonorrhea being reported. If control is to be accelerated, additional case-finding measures must be established.

In hospitals, clinics, and physicians' offices, urine specimens of large numbers of patients are routinely examined for albumin, sugar, and so on. If, at this same time, gonorrhea could be found by examination of these urine specimens, an economical and simple case-finding aid would be available; a rapid screening procedure for detection of gonorrhea suspects would be provided. This paper presents the results obtained in a preliminary study of macroscopic inspection and microscopic examination of the sediment of urine specimens for the detection of gonorrhea in patients from a selected clinic group and from an unselected screening line group.

Methods

Urine specimens were collected in flat-bottomed specimen bottles. One to two cubic centi-

meters of 10-percent acetic acid was added to the fresh urine specimens, which were then macroscopically inspected. An opinion was recorded as to the presumptive presence of pus or shreds in the urine specimen. If shreds or pus were present, the specimen was considered presumptively positive for gonorrhea.

The urine specimen was then allowed to sit for at least 1 hour. After this period it was decanted and a spread was prepared from the sediment. The spread was air-dried, stained with a Gram's stain, and examined under an oil-immersion lens for the presence of gram-negative intracellular diplococci. Urine specimens which had been allowed to stand for any period before initial visual inspection were swirled before acidifying and then were allowed to stand for at least an hour before microscopic examination of the sediment.

When a microscopically positive sediment was found in a urine specimen and a diagnosis of gonorrhea had not been established in the patient prior to the urine test, the patient was re-examined bacteriologically. The diagnosis of gonorrhea was established or confirmed in all patients with positive sediment findings by urethral or cervical spread or, if indicated, by culture.

Results

The selected population group consisted of male patients who were examined in a venereal disease clinic. Of this group, 68 had a frank urethral discharge in which gonococci could be demonstrated. Using the test technique de-

Dr. Taggart is acting chief, preventable and chronic diseases division, bureau of disease control, District of Columbia Department of Public Health, Washington, D. C. This paper was presented at the Symposium on Recent Advances in the Study of Venereal Diseases, April 29-30, 1954.

scribed in this paper, 52 of these 68 patients, or approximately 75 percent, were found to have gram-negative intracellular cocci in the sediment of their urine specimens; these urine specimens also had been considered positive for gonorrhea by sample inspection, utilizing the technique described for screening. Thirty-two of these venereal disease clinic patients had no urethral discharge and had been considered clinically negative both by history and physical examination. However, in 3 of the patients (approximately 10 percent), positive findings in the sediment were obtained by microscopic examination (2 were positive and 1 was negative by macroscopic inspection). These diagnoses of gonorrhea were confirmed by bacteriological study of urethral scrapings.

In order to determine the effectiveness of this simple macroscopic technique under conditions in which patients were not appearing primarily for venereal disease diagnosis and treatment, it was applied to a different type of patient body. This group consisted of patients of the outpatient service of the District of Columbia General Hospital. Urine specimens from these patients are collected routinely as a part of their initial examination. These patients were being seen for various medical and surgical complaints, and without this examination would have been considered free of gonorrhea. The

urine specimens were examined by the test technique under consideration and the discovery rate of gonorrhea in this group was 15.0 percent in the males and 6.8 percent in the females. Demonstration of gonococci by urethral or cervical spread or culture was possible in all of these patients. Because this study was of a preliminary investigative nature, sugar fermentation studies for definitive bacteriological diagnoses were not considered necessary at this time.

The findings obtained in both groups are presented in the accompanying table.

Discussion

The results of this study of the detection of gonorrhea suspects by macroscopic examination of the sediment of urine specimens appear encouraging, and suggest the desirability of further study to determine whether this method might become practicable.

It would appear that a technique of macroscopic inspection followed by microscopic examination of sediment of presumptively positive urine specimens will establish a diagnosis of gonorrhea in approximately three-fourths of an infected group.

Culturing the urinary sediment of all patients would no doubt have raised the percentage

¹ Diagnosed bacteriologically as having gonorrhea, subsequent to presumptive diagnosis of gonorrhea based on examination of urine specimens.

of infected persons found. However, the technical difficulties and increased cost entailed by this procedure would, in most cases, not be warranted. Of greater significance to the gonorrhea control program is the fact that a simple method of screening large numbers of individuals who are infected with gonorrhea, but who have not been motivated to seek specific medical care, should be of value in the public health control of gonorrhea. From experimental inoculation studies with gonorrhea it is known that not all patients have the profuse outpouring of pus and urethral discomfort that are considered characteristic of the disease. It is this group, not sufficiently disturbed by the infection to seek specific care, which might be discovered, especially if the portion of the population in which the prevalence of gonorrhea might be expected to be high were screened.

The finding of an infection rate of 15 percent among a clinic group consisting of patients who were not destined for a type of examination which could be expected to bring them to treat-

ment for gonorrhea suggests the potential importance of this simple method of urine examination. It would appear that the preliminary studies herein described are sufficiently valuable to suggest the desirability of further investigation. It is known that gonorrhea thus far has been relatively resistant to various control procedures. In spite of simple, sure cure the disease has not responded to our control efforts in the same way as syphilis. One of the stumbling blocks has been the lack of a simple case-finding device. These preliminary results would seem to merit further investigation.

Summary

A simple, routine screening procedure for a presumptive diagnosis of gonorrhea by a macroscopic examination of urine samples has been described. In a high-prevalence population, such a technique should be an aid in case finding in a gonorrhea control program.

World Health Day, April 7, 1955

"Clean Water for Better Health" is the theme of the seventh anniversary celebration of the World Health Organization.

The "clean water" theme emphasizes the basic sanitary engineering services which construct safe water supplies and sewage disposal systems for the people of the world. United States membership in WHO helps to develop such long-term worldwide health programs. Short-term health programs abroad are promoted by United States health personnel assigned by the Foreign Operations Administration to health ministries.

The clean water program in the United States was estimated in the President's Economic Report to the Congress January 28, 1954, as requiring \$6 billion for water systems and \$9 billion for new sewers and waste facilities by 1960.

Advances in America's clean water program are supported by water pollution control activities of industry and of local, State, and Federal Government agencies. The Water Pollution Control Act of 1948 is the major instrument for coordinating this work. Research on water pollution control is conducted cooperatively by the Public Health Service Robert A. Taft Sanitary Engineering Center at Cincinnati, the National Technical Task Committee on Industrial Wastes (supported by private industry), by universities, and other institutions.

Mortality and Marital Status

By DEWEY SHURTLEFF, M.P.H.

A NUMBER of analyses have shown that married people live longer than single people. The most recent analysis published for the United States was for 1940 (1), and the figures clearly showed the lower mortality rates for the married population. In the years since 1940, there has been a tremendous change in mortality rates and a distinct increase in the married proportion of the population. In the light of these changes, it is of particular interest to reexamine the mortality rates by marital status based on the 1950 census.

Population Base

In the 1950 census (2), data on marital status were based on the replies to the question, "Is he (she) now married, widowed, divorced, separated, or has he never been married?" The question referred to status at the time of enumeration. Persons classified as married comprise, therefore, both those who have been married only once, those who remarried after having been widowed or divorced, and persons reported as separated. Those reported as never married or with annulled marriages were classified as single. Since it is probable that some divorced persons were reported as single, married, or widowed, the census returns doubtless

understated somewhat the actual number of divorced persons who have not remarried.

The distribution of the population by marital status for each age-sex group is shown in table 1. Most men were single at ages 20-24 years, but they soon got married; 3 out of 4 men were married at ages 25-29. Two out of three women were married by the time they were 20-24 years old, and at ages 25-29, 4 out of 5 were married. The peak percentage married was 87.1 for men at ages 40-44 and 86.2 for women at 30-34 years. From 35 years on for men and from 30 years on for women the single proportion of the population remained nearly constant, close to 10 percent. The proportion widowed increased with advancing age, much more so for women than for men. The peak percentage divorced was 3.0 for men at ages 50-54 and 3.7 for women at 40-44 years.

Mortality Data

Marital status at the time of death is reported routinely on the death certificate. Deaths classified in the same categories as the enumerated population are now available for 1949, 1950, and 1951; rates shown in this paper are based on the average annual number of deaths for these 3 years and on the population enumerated in the 1950 census.

The death rates are shown by marital status, age, and sex in table 2. To summarize, if the 1949-51 death rates for age 20 and over by marital status, age, and sex had occurred in a standard population distributed by age like the

Mr. Shurtleff is an analytical statistician in the Mortality Analysis Section, National Office of Vital Statistics, Public Health Service.

population for each sex enumerated in 1940, taking the expected numbers of deaths for the married as 100, the index numbers would be:

	<i>Single</i>	<i>Married</i>	<i>Widowed</i>	<i>Divorced</i>
Male.....	163	100	185	207
Female.....	124	100	155	155

These figures summarize the mortality differences among the marital classes. The lowest mortality is still found for the married population, the next most favorable in the single group, and the highest among the widowed and divorced. The differences in mortality between the married and the unmarried are greater for men than for women.

Mortality by Marital Status, Age, and Sex

It is evident from table 2 that all through the age span, for men and for women, the death rates are lower for the married than for the single, widowed, or divorced. For both men and women in every age group 20 years and over, the mortality rank-order of three of the marital classes generally remains the same: the lowest for the married, the next for the single, and the highest for the divorced. The rank-order of the widowed class shifts with advancing age. The death rate for widowers is the highest of the four marital classes at the early ages, but at ages beyond 60 years, the mortality of widowers is less than that of either single or divorced men. A similar pattern holds for women, although the death rates for widows do not fall below that of the divorced until after age 60.

The differences in death rates may be due, in part, to the greater tendency of healthier people to marry. The evidence for selection as a factor in the differences in rates may be seen more clearly by examining the relative differences in rates between the unmarried and the married at each age. Taking the mortality of the married as 100 in each age group, the chart shows the age-specific death rates for the single, widowed, and divorced expressed as percentages of the corresponding rate for the married. The differences are the greatest between married and unmarried men between the ages of 25 and 44. Similarly, the differences between married and unmarried women are greatest between the ages of 25 and 34. Beyond these ages the curves

SOURCE: Table 102 of reference 2.

show a tendency to converge, more so for women than for men. At the older ages there is less difference in mortality between the married and the unmarried. The chart also shows that differences in rates between the married and the unmarried, in each group, are greater for men than for women.

The persistent differences in rates between the married and unmarried suggest that the married state itself may directly affect mortality. However, the available data are not sufficient to shed light on the many questions that would have to be answered before reaching an understanding of the complex factors involved in the differing mortalities of the marital classes.

For each of the four marital classes, as can be seen in table 2, the death rates for men are

higher than those for women in every age group between 20 and 74. The largest relative difference in rate between the sexes appears in each age group under 60 for the divorced and then in each age group 60 and over for the single. The smallest difference appears in each age group for the married. The ratio of the rate for divorced men to that for divorcees climbs from 2.2 at ages 25-34 to 2.9 at ages 45-54 and declines to 1.6 at ages 70-74. The ratio of the rate for bachelors to that for spinsters rises from 1.6 at ages 25-34 to 2.6 at ages 55-59 and then falls to 1.9 at ages 70-74. From 25 to 64 years, in each age group, the rate for widowers is close to double that for widows, and then it declines to 1.5 times at ages 70-74. The death rate for husbands is 1.4 times that for wives at ages 25-34 and 35-44, increases to 1.7 times at ages 55-59, and drops back to 1.4 times at ages 70-74.

A Look Back at 1940

In the United States, more people than ever before are married. In 1890, the earliest year Federal census figures are available for marital status (2), 2 out of 3 persons 20 years or older were married. By 1950 this proportion had increased to 3 out of 4. The big jump in the

percentage married came in the last 10 years—from 68.8 percent in 1940 to 74.2 in 1950. For comparison, the percentage distributions by marital status of the male and female populations 20 years and over are given for 1940 and 1950.

	Male		Female	
	1950	1940	1950	1940
Single.....	17.0	23.9	11.8	17.0
Married.....	76.1	69.7	72.3	68.0
Widowed.....	4.7	5.0	13.3	13.2
Divorced.....	2.2	1.4	2.7	1.9

Among both men and women, with few exceptions, in each 5-year age group from 20 to 84 years, the percent single and percent widowed decreased, and the percent married and the percent divorced increased between 1940 and 1950.

The mortality by marital status for the United States in 1940 based on the 1940 census has been published (1). In the 10 years since 1940 there has been a marked decrease in death rate for both men and women at every age. The number of deaths expected in the standard population aged 20 and over—computed in the same manner as described on page 248—decreased a seventh for men and a fourth for women. The percent changes in expected

Table 2. Death rates by marital status, age, and sex; United States, 3-year average, 1949-51

(Exclusive of deaths among armed forces overseas. Rates per 1,000 population in each specified group enumerated as of April 1, 1950.)

75 and over.....	119.4	137.3	100.3	139.0	173.3	101.6	103.6	76.0	106.2	129.2

¹ Includes deaths for which marital status was not stated.

² Includes deaths for which age was not stated.

³ Rates for "Total" and "Single" are based on deaths and population at ages 0-19 years. Rates for "Married," "Widowed," and "Divorced" are based on deaths and population at ages 15-19 years.

Age-specific death rates for each marital-sex class as percentages of death rates for married persons of corresponding age and sex; United States, 3-year average, 1949-51.

deaths from 1940 to 1949-51 by marital status were:

	Male	Female
Total.....	-14	-24
Single.....	1	-21
Married.....	-13	-25
Widowed.....	-16	-23
Divorced.....	-16	-33

All but one of the marital-sex classes benefited from the improvement in mortality conditions. Expected deaths for bachelors were about the same in 1949-51 as 10 years ago.

Comparison of the age-specific death rates for 1940 with those for 1949-51 by marital status and sex shows that, except for bachelors, declines were recorded for each marital-sex class at all ages. The percentage changes in death rates between 1940 and 1949-51 are shown in table 3.

Between the two periods, the death rate for women dropped about one-fifth or more for each age group in each marital class, with the greatest drops recorded for the youngest years. At ages 20-34 the rates for wives were cut in half. The death rates for the married, widowed, and divorced men were lower at every age in 1949-51 than in 1940, with the greatest decreases, about a third, recorded for ages under 35. Middle-aged and elderly bachelors did not share in the general mortality improvement of the 10-year period.

The changes in mortality among the marital classes since 1940 can also be seen by comparing the summary measures for 1940 with those for 1949-51 previously described. The 1940 percentages relating the expected number of deaths of each marital-sex class to the expected num-

Table 3. Percentage changes in death rates between 1940 and 1949-51, by marital status, age, and sex: United States

55-59.....	-23	-24	-20	-28
60-64.....	-24	-21	-19	-29
65-69.....	-24	-23	-22	-31
70-74.....	-19	-21	-21	-34
75 and over.....	-18	-18	-17	-35

ber of deaths of married persons of the same sex are:

	<i>Single</i>	<i>Married</i>	<i>Widowed</i>	<i>Divorced</i>
Male_-----	141	100	192	215
Female-----	117	100	151	173

The relative mortality of the marital classes did not change in the decade following 1940—the lowest mortality was for the married population, the next for the single group, and the highest among the widowed and divorced—but the percentage excesses in the mortality of the unmarried compared with the married shifted somewhat. The excess in the mortality of bachelors over that of husbands is 41 percent for 1940 and 63 percent for 1949–51. The excess in the mortality of spinsters over that of wives is 17 percent for 1940 and 24 percent for 1949–51. The corresponding excesses in mortality of divorced persons and of widowers are smaller in 1949–51 than in 1940; the excesses in mortality of widows are about the same in the two periods. Such changes have probably resulted from changing factors influencing marital status as well as mortality.

Summary

Among both men and women at every age, the married have lower death rates than the single, widowed, or divorced. When allowance is made for the variation in age distribution, the mortality of bachelors is nearly two-thirds greater than that of husbands, and the mortality of widowed and divorced men is about double that of husbands. The differences are not as large for women. The mortality of spinsters is a fourth again as high as that of wives, while the mortality of widows and divorcees is half again as high. The available data do not afford an interpretation of the nature of selection of persons into the marital groups, and the effect of marriage itself on mortality rates.

Home Safety Booklet Available

An 8-page booklet, entitled "Home Safety Principles," has been prepared from copy published by the National Association of Home Builders in cooperation with the National Safety Council and the Public Health Service in the magazine, *Practical Builder*.

The principles enumerated in this booklet cover general construction and safety inside and outside the house. Specific attention is given to safety matters in the yard, the exterior of the house and garage, roof and chimney, crawl space, kitchen, living, dining and bedrooms, bathroom, closets and storage space, electrical, plumbing, heating, and air conditioning systems. The booklet also features a home safety check list.

Most of the principles can be applied with little or no additional cost. If followed, they should contribute significantly to the reduction of accidental home injuries and deaths.

Copies of the reprint are available from the Division of Engineering Services, Bureau of State Services, Public Health Service, Washington 25, D. C.

A New Organism Resembling *P. tularensis* Isolated From Water

By CARL L. LARSON, M.D., WILLIAM WICHT,
and WILLIAM L. JELLISON, Ph.D.

THE DEMONSTRATION of the presence of *Pasteurella tularensis* in ponds, rivers, and streams in northwestern United States (1) prompted continued study on the distribution of *P. tularensis* in such waters, especially where there have been reports of epizootics in aquatic mammals.

During the course of the studies, an organism, apparently not described in the literature, was detected in a water sample obtained from Utah. The purpose of this paper is to describe this organism, for which we propose the name *Pasteurella novicida* sp. nov. In correspondence and in the exchange of cultures, this organism has been referred to as Utah 112.

Isolation of the Organism

A turbid water sample collected from Ogden Bay Bird Refuge, near Ogden, Utah, was received September 12, 1950, from Dr. Jessup B. Low of the Utah Cooperative Wildlife Research Unit. Muskrats had been found dead in the immediate area where the sample was collected. Two guinea pigs were each injected

intraperitoneally with 10 ml. of this sample, 4 white mice with 2 ml. each intraperitoneally, and 4 white mice with 2 ml. each subcutaneously.

One guinea pig was found dead 6 days after inoculation. Indistinct foci on the liver and spleen were suggestive of tularemia. The other guinea pig, moribund later in the day, was sacrificed and its heart blood placed on glucose-cystine-blood agar. On necropsy, numerous foci of necrosis were observed on the liver and spleen. These lesions were also suggestive of tularemia, and a tentative diagnosis of that disease was made. Cultures from this guinea pig gave pure cultures of the organism under consideration.

One of the mice died on the fourth day post-inoculation and two more on the sixth day. White foci were noted on the spleen of one mouse, and cultures were obtained from the tissues of both mice that died 6 days after injection. The cultures were similar to those isolated from the guinea pig.

Suspensions of the bacterium failed on repeated tests to agglutinate in specific anti-tularensis serum, and tissues of animals which died following injection with the original water sample, as well as tissues from serially infected animals, gave negative Ascoli tests (2) with the same serum.

The failure of the serologic tests to identify the organism as *P. tularensis* was puzzling since the time of death of test animals and the gross

Dr. Larson is the director, Mr. Wicht is a laboratory technician, and Dr. Jellison is the parasitologist, Rocky Mountain Laboratory, National Microbiological Institute, Public Health Service.

lesions were suggestive of tularemia; also, the growth of the organism on glucose-cystine-blood agar and the appearance of the organism from culture and tissue smears, when stained with carbolthionin, greatly resembled *P. tularensis*.

Materials and Methods

The methods used in identification of this organism are largely those recommended in the Manual of Methods for Pure Culture Study of Bacteria (3). However, some variations have been necessary, since the organism does not grow on certain of the media which are ordinarily employed for biochemical tests. Routinely, glucose-cystine-blood agar was used for maintenance of the organism. The proteose-peptone broth of Snyder and his co-workers (4) was employed as the liquid medium. For fermentation tests, filter-sterilized carbohydrates and polyhydroxyalcohols were added in 2-percent concentration, and bromthymol blue was added as indicator. Experimental animals were from stock maintained at the Rocky Mountain Laboratory. Embryonated eggs were inoculated after incubation at 37° C. for 7 days.

Ascoli tests were performed, using bacterial or tissue suspensions treated with ether, according to methods previously described (2).

Organisms used in this study included the bacterium isolated from water from Ogden Bay, *P. tularensis* (strains 453 and 454, which were isolated from streams in the Bitterroot Valley, Mont.), as well as *Pasteurella pestis*, *Pasteurella multocida*, and *Pasteurella pseudotuberculosis*, which are maintained at this laboratory.

Results

The newly isolated bacteria under study are nonmotile, gram-negative rods, which do not form spores. There is some tendency toward bipolar staining, but this is not marked and does not serve as a distinguishing feature. No flagellae are observed. No definite capsule is apparent in preparations from artificial media stained with carbolthionin, Giemsa, or Wayson's stains, although clear areas are observed around cells in smears from tissues of infected animals. In smears prepared from spleens of guinea pigs

and stained with carbolthionin, the organisms are ovoid to coccoid, measure 0.28 μ in length and 0.20 to 0.28 μ in width, and are arranged singly and in small clusters. When grown in liquid media they are 0.7 μ in width and 1.7 μ in length, and are predominantly short, thick rods with slightly bulging sides. They are arranged singly or in pairs. A few coccoid forms are present. If the bacteria are grown in broth containing 3 percent NaCl, the organisms are found to be pleomorphic, and rods as long as 4.2 μ are noted. When grown on solid media, the organisms measure 0.47 μ to 0.94 μ in length and 0.47 μ in width. These examinations were made by phase microscopy with organisms grown at 37° C. for 24 or 48 hours. Broth cultures were examined for motility after incubation for 18, 24, and 48 hours at 25° C. and 37° C., by both light- and dark-field microscopy.

On primary isolation, the culture grows well on glucose-cystine-blood agar, but not on nutrient agar (Difco). Cultures made directly from animal tissues by smearing liver or spleen upon the surface of horsemeat-infusion agar do not grow except in the immediate vicinity of small pieces of tissue that adhere to the medium. After 11 serial passages in guinea pigs, *P. novicida* still could not be isolated on media lacking added cystine, yeast extract, or whole blood. Plating of serial dilutions on the surface of various media indicates that glucose-cystine-blood agar, glucose-cystine agar, blood agar, or yeast-extract agar are about equally suitable media. No growth occurred in plain horsemeat-infusion agar, with or without addition of dextrose, even when as many as 50,000 organisms were present in the inoculum.

On glucose-cystine-blood agar, well-separated colonies may attain 8 mm. in diameter after 72 hours' incubation. They are gray with a definite blue cast, smooth, slightly elevated, glistening, amorphous, and have entire edges. The colonies are butyrous or viscid and are easily emulsified in water to form a homogeneous suspension. Colonies average about 4 mm. in diameter on blood agar but otherwise resemble those described above. On glucose-cystine agar, they average 6 to 7 mm. in diameter and are translucent. On yeast-extract agar, the colonies are about 3 mm. in diameter, clear, convex, glistening, and with smooth edges. Growth

is moderate in 24 hours at 37° C. on slanted media, and isolated colonies have characteristics similar to those described for each of the above media. The growth is filiform and tends to pile up at the edges. There is no hemolysis on blood agar.

In deep agar shakes of media containing yeast extract or cystine incubated for 8 days at room temperature at 30° C. and 37° C., the organisms grow on the surface and to a depth not exceeding 0.7 cm. below the surface. The surface colonies approximate 5 mm. in diameter whereas those growing within the agar are 1 mm. or less.

In the fluid medium employed (4), growth is abundant, producing a moderately uniform turbidity. There is no pellicle or surface growth. A slight deposit develops, which may be disintegrated by shaking. No growth can be seen on raw potato.

Fermentation

The first isolate of *P. novicida* was found to ferment dextrose, sucrose, levulose, and mannose, with production of acid but no gas. A culture isolated from the 11th passage in guinea pigs was tested in Snyder's medium containing 2-percent concentrations of the various substrates and bromthymol blue to determine the fermentative reactions of the organism. The medium was dispensed in 25-ml. volumes in 100-ml. flasks and incubated at 37° C.

Two cultures of *P. tularensis* (isolates 453 and 454) were studied under identical circumstances. Each flask of medium was inoculated with 1 ml. of suspension of organisms grown in Snyder's medium for 24 hours at 37° C. Flasks of Snyder's medium were included as uninoculated controls and flasks containing indicator but no added substrate served as inoculated controls. The color changes were noted and the pH determined, with the aid of a pH meter, 4 and 14 days after incubation. The results of pH determinations are presented in table 1.

Additional carbohydrates and polyhydroxy-alcohols not included in the table were tested. These were inulin, rhamnose, trehalose, sorbitol, arabinose, adonitol, dextrin, melizitose, salicin, inositol, xylose, lactose, esculin, raffinose, galactose, mannitol, and dulcitol. The final pH attained by media containing these substances was 7.3 to 7.6 for *P. tularensis* isolate 453, 7.4 to 7.8

Table 1. Comparative fermentation studies on *Pasteurella tularensis* and *Pasteurella novicida*

Substrate	pH reactions of media after 4 and 14 days' incubation with—					
	<i>P. tularensis</i> (453)		<i>P. tularensis</i> (454)		<i>P. novicida</i>	
	4 days	14 days	4 days	14 days	4 days	14 days
Sucrose---	7.6	7.5	7.6	7.6	5.6	5.5
Dextrose---	6.9	6.5	6.9	6.8	5.7	5.6
Levulose---	6.6	5.8	6.5	6.2	5.7	5.2
Mannose---	6.9	6.7	6.9	6.6	5.8	5.5
Glycerol---	7.6	7.6	7.5	7.6	7.3	6.9
Maltose---	7.6	7.5	7.6	7.6	7.7	7.6
Inoculated control---	7.5	7.5	7.5	7.6	7.7	7.7

for *P. tularensis* isolate 454, and 7.4 to 7.7 for *P. novicida*. Fermentation of sucrose by *P. novicida* serves to differentiate it from *P. tularensis*.

The effect of fermentable sugars upon the growth of the organism was determined. Cultures were made in Snyder's medium containing dextrose, sucrose, maltose, and lactose, all with bromthymol blue as indicator. After 3 days' incubation at 37° C., when the color of the medium indicated that fermentation of dextrose and sucrose had taken place, serial tenfold dilutions were made of the bacterial suspensions, and counts were made on glucose-cystine-blood agar. The bacterial counts of each of the media were in very close agreement, being 25×10^8 and 27×10^8 for media containing dextrose and sucrose, respectively, and 24×10^8 and 19×10^8 for those with maltose and lactose, respectively. Thus, the presence of fermentable sugars had no effect on the growth of *P. novicida*.

Biochemical Reactions

The following biochemical reactions were observed: nitrates not reduced to nitrites; indol negative by Kovac's method; H₂S positive by lead acetate paper strips; ammonia not produced; methylene blue reduced, catalase positive; gelatin contained no added cystine supported growth but was not liquefied; litmus milk unchanged; methyl red and Voges-Proskauer negative, although growth was manifest

in the medium; no growth on McConkey's medium.

The resistance of the organism, comparable to that of *P. tularensis*, is not great. Suspensions containing 4×10^8 bacteria in saline were killed in 10 minutes by exposure to a temperature of 60° C. and in 20 minutes by exposure to 1 per cent phenol. Cultures of *P. novicida* and *P. tularensis* (453 and 454) were grown on glucose-cystine-blood agar at temperatures of 25°, 32°, 37°, and 41° C. Three subcultures were made during an observation period of 16 days. None of the strains of organisms was affected by exposure to the limits of temperature selected since there was confluent growth on each of the agar slants at the termination of the experiment.

No evidence for the presence of a soluble toxin or for the filterability of the organism was found. A culture of the organism was grown in Snyder's medium at 37° C. for 48 hours and filtered through a sintered glass filter (grade UF). The first aliquot of 10 ml. was discarded. The remainder of the filtrate was collected and tested for sterility. No growth occurred on glucose-cystine-blood agar plates or on Snyder's medium. Mice and guinea pigs inoculated intraperitoneally with 0.1 and 5.0 ml., respectively, of this filtrate were not infected.

Pathogenicity

P. novicida is pathogenic for a wide range of experimental animals. The pathogenicity for white mice and guinea pigs is shown in table 2. As few as 50 organisms injected subcutaneously into mice caused death, whereas as few as 5 organisms administered intraperitoneally caused death in 3 of 4 mice. Small numbers of organisms were also shown to be lethal for guinea pigs by intraperitoneal injection. Hamsters were as susceptible as mice and guinea pigs and showed more distinctive gross lesions. Titrations of cultures and tissues from infected animals or embryonated eggs demonstrated that suspensions containing two bacteria, as determined by growth on glucose-cystine-blood agar plates, were capable of producing lethal infections in 7-day-old embryonated eggs. The disease produced in embryos was fatal within 2 to 7 days.

There was considerable resistance to infection in rabbits, white rats, and pigeons, and

² No deaths among animals inoculated with 10⁻⁵, 10⁻⁶, or 10⁻⁷ dilutions.

³ Numerator, number died; denominator, number inoculated.

large numbers of organisms were needed to produce signs of illness and death. Six million organisms caused death within 4 days of three pigeons inoculated intramuscularly, but 6×10^5 organisms failed to produce illness in a similar group of birds. Rabbits infected with as few as 3×10^4 organisms succumbed if inoculated either intraperitoneally or subcutaneously, but some lived as long as 25 days. White rats were susceptible to large doses of organisms administered intraperitoneally (3×10^7) but not to similar amounts given subcutaneously.

There were no pathognomonic lesions in embryonated eggs examined after death of the embryo, but hemorrhages and congestion were commonly noted. Mice inoculated subcutaneously showed congestion of the subcutaneous tissues, hemorrhages at the site of inoculation, with enlargement and congestion of the local lymph nodes, hemorrhages and congestion of

the lungs, and enlargement of the spleen, with multiple small foci of necrosis. There were no gross lesions in the liver. The subcutaneous tissue of guinea pigs was hemorrhagic and congested, the local lymph nodes were enlarged and hemorrhagic, the spleen was enlarged, containing many small, raised gray foci of necrosis and was usually covered with a gray exudate. The liver contained few to many foci of necrosis. The lungs were congested and hemorrhagic and exhibited foci of necrosis in many instances. The lesions noted in rabbits, white rats, and hamsters were essentially similar to those noted in white mice and guinea pigs. In one rabbit, surviving for 25 days after infection, many large caseous areas of necrosis were found in the lungs.

Serologic Reactions

Agglutination and precipitin tests were performed with serums from rabbits immunized by repeated intravenous inoculation of formalin-killed suspensions of *P. tularensis*, *P. novicida*, *P. pestis*, *P. pseudotuberculosis*, and *P. multocida*. A formalin-killed suspension of each of the organisms was employed for agglutination tests. Precipitin tests were done with the supernatant fluid obtained after suspensions of the organisms in saline had been treated with two volumes of ether, and the aqueous phase centrifuged and harvested (2). The tests were incubated at 37° C. for 4 hours and placed in the refrigerator overnight before being read the following morning.

It was found that formalin-killed suspensions of *P. novicida* reacted in the agglutination test with serum prepared against the homologous organism but not with serums prepared against the heterologous organisms. Similarly, the immune serum prepared against *P. novicida* agglutinated suspensions of *P. novicida* to a titer of 1:320, *P. tularensis* and *P. pseudotuberculosis* to titers of 1:10 only and failed to react with *P. pestis* and *P. multocida*.

The several serums were tested for the presence of precipitins against *P. novicida*. The *P. novicida* antigen employed failed to react with serums from rabbits immunized with *P. pseudotuberculosis* and *P. multocida*, but reacted with undiluted serums specific for *P.*

pestis and *P. tularensis* and to a titer of 1:32 against homologous serum. The anti-novicida serum precipitated with antigens derived from *P. pestis* and *P. tularensis* in dilution of 1:4, from *P. pseudotuberculosis* to a dilution of 1:2, from *P. novicida* to a titer of 1:32, and failed to precipitate antigen from *P. multocida*. When dilutions of antigen prepared from *P. novicida* were tested against whole serums in the precipitin test, the antigen did not react with serums specific for *P. multocida* and *P. pseudotuberculosis* but reacted at dilutions of 1:4 with serums against *P. pestis* and *P. tularensis* and at a dilution of 1:64 against the homologous serum. In general, the serums from rabbits immunized against formalin-killed antigens gave specific reactions in both agglutination and precipitin tests.

Precipitin tests were performed with serums from rabbits immunized with suspensions of *P. novicida* and *P. tularensis* killed: (a) by heating at 60° C. for 30 minutes, (b) by addition of 2 volumes of ether, and (c) by 0.2 percent formalin or 0.5 percent phenol. Antigens were obtained by extraction with ether. The results given in table 3 indicate that the antibodies produced are relatively specific for each bacterial species and do not appear to be significantly varied by the type of treatment afforded the antigen employed to immunize the animals.

Table 3. Results of precipitin tests with serums of rabbits sensitized with variously treated antigens

Discussion

The organism described has certain characteristics that indicate a relation to the organisms contained in the family Parvobacteriaceae, but it cannot be associated directly with any of the various tribes within the family. Morphologically, it has considerable resemblance to *P. tularensis*, being similar in microscopic appearance, in showing considerable dependence upon growth factors in blood, yeast extract, or cystine, and in characteristic colonial growth on glucose-cystine-blood agar. The lesions produced in experimental animals and the wide range of hosts susceptible to infection increase the apparent resemblance. Both may be found in natural waters of the western States. They differ markedly, however, in immunological characteristics and may be distinguished by either agglutination or precipitin tests. In addition, *P. novicida* ferments sucrose, whereas *P. tularensis* does not.

There has been considerable discussion as to whether or not the etiological agent of tularemia is justifiably included in the genus *Pasteurella*. At present, it would appear best to leave it in the genus *Bacterium* until its taxonomic position is clarified. We would prefer to place the newly isolated organism in the genus *Bacterium* for the same reason. However, the genus name *Bacterium* is a "rejected generic name" by recent (1954) action of the International Committee on Bacteriological Nomenclature (5) so it is not available. The only alternative to the use of *Pasteurella* would be to establish a new genus name for the two organisms. This we are not prepared to do at this time.

Further examination of natural waters in the western United States, including Ogden Bay, has not resulted in additional isolations of *P.*

novicida. Many cultural studies of the laboratory animals maintained at the Rocky Mountain Laboratory have not revealed the organism to be present in the animal colonies, justifying the conclusion that the isolation of *P. novicida* from guinea pigs and mice inoculated with water represented a valid isolation from the water sample involved.

Summary

A micro-organism highly pathogenic for mice, hamsters, guinea pigs, and rabbits has been isolated from a water sample collected in Ogden Bay, Utah. In gross appearance of cultures, microscopic appearance, and pathogenicity, it closely resembles *Pasteurella tularensis*. It may be distinguished, however, from *P. tularensis* by fermentation studies and by serologic tests. The organism is described and the name *Pasteurella novicida* sp. nov. is proposed.

Rheumatic Fever Management

Notes on a panel discussion at the Second World Congress of Cardiology, Washington, D. C., September 14, 1954. Chairman, T. Duckett Jones, M.D., medical director of the Helen Hay Whitney Foundation, New York City (died November 22, 1954). Co-chairman, Maurice Campbell, M.D., London, England. Panel members: Edward F. Bland, M.D., Massachusetts General Hospital, Boston. Albert Dorfman, M.D., Chicago. John D. Keith, M.D., Toronto, Canada. Charles H. Rammelkamp, M.D., Cleveland, Ohio.

. . .

IS RHEUMATIC FEVER declining in prevalence and incidence? Clinical evidence, such as the relatively rare occurrence of severe chorea, or St. Vitus' dance, suggests a decline in severity. Statistical evidence, such as the decline in cases in all age groups reported in Toronto by Dr. John D. Keith, suggests a decline in prevalence. The accompanying chart, prepared by the National Heart Institute of the Public Health Service, also suggests a decline in the number of cases and severity of rheumatic heart disease. Nevertheless, Dr. T. Duckett Jones observed that the apparent decline may result from improved environmental conditions, such as heating and nutrition, rather than from any genuine change in the organic process. He stated there has been no change in the ability to contract rheumatic fever. And he felt the decline in cases may be more apparent than real. As he put it, when successful heart surgery was announced, rheumatic cardiac cases more often sought relief and advice. He believed that a decrease in crowding in the home has reduced exposure to streptococcal infections. It was noted also that the use of antibiotics has greatly lessened the incidence and possibly the duration of recurrences.

Diagnosis

With regard to methods of diagnosing rheumatic fever, the panel agreed that no specific laboratory test is entirely satisfactory. It concluded that, although sedimentation rate tests were very helpful, accurate diagnosis still depends primarily upon direct evidence of the patient's condition and history. However, it was noted that many patients with serious rheumatic heart disease give no history of the swelling, redness, and pain of the joints which are often typical clinical symptoms. For this reason, considerable interest was expressed in the work of Dr. May Wilson, who has undertaken to determine whether fluoroscopic observation of progressive enlargement of the heart chambers may be a practical diagnostic aid. The panel seemed to agree that a thin, pinched, weary appearance in the child is a distinct clue to rheumatic fever activity.

Dr. Edward F. Bland reported that of 1,000 rheumatic fever patients observed since childhood in the past 20 years somewhat fewer than a third had died. Of these, 80 percent had died of congestive heart failure. Ten percent had died of acute or subacute bacterial endocarditis. The remainder had died of other causes, about half of which were not related to the chronic affliction. He observed also that the surviving patients had been treated successively by salicylates, sulfadiazine, and penicillin, and that many now might have their health and expectancy protected by valve surgery.

Control

Dr. Charles H. Rammelkamp asserted that when sulfadiazine or penicillin failed to prevent rheumatic fever the failure often lay with the patient's refusal to follow prescribed orders rather than with the effects of the compounds.

Heart disease (mainly rheumatic) and rheumatic fever, age-specific death rates per 100,000 persons aged 5-24, United States, 1915-50.

He asserted also that, since the average child experiences a streptococcal infection about once every 4 or 5 years, the best method of preventing rheumatic fever, a potential result of any streptococcal infection, is to eradicate the streptococci. Such eradication can be achieved by administering compounds not only to the infected child but also to other exposed members of the family. He noted that sulfadiazine used against the streptococcal infection is ineffective against a rheumatic fever attack. Penicillin is the drug of choice.

Dr. Jones commented that a statement on prophylaxis for rheumatic fever, issued by the American Heart Association, is being revised and that a new statement is forthcoming. It was advised that administration of a depositional form of penicillin about a month prior to a valve operation for rheumatic fever patients might protect against postoperative flareup of the disease.

Fundamental Studies

Immediately before the panel discussion, Dr. Lewis Thomas of Minneapolis described studies which explored the fibrinoid processes involved in rheumatic fever, lupus erythematosus, and related collagen diseases.

The process which develops from a streptococcal infection and leads to rheumatic fever and cardiac injury was the subject of a paper presented at the congress by Dr. Aaron Kellner and Dr. Theodore Robertson of New York. They observed that a proteolytic enzyme produced by many strains of group A streptococci acts as a powerful poison upon the heart. This enzyme was isolated in crystalline form by Dr. Stuart Elliott of the Rockefeller Institute.

• • •

NOTE: The American Heart Association's revised statement on rheumatic fever prophylaxis will appear in the April issue of Public Health Reports.

Important implications for civil defense lie in this study of 6,343 case histories of radiation injuries, flash burns, lacerations, and contusions—received outdoors or indoors within a 2.3-mile radius of ground center.

Atomic Bomb Injuries Among Survivors in Hiroshima

By MARDELLE L. REYNOLDS, A.B., and FRANCIS X. LYNCH

THE PRIMARY PURPOSE of this paper is to present the results of a study of atomic bomb injuries in relation to the type of protection of survivors who were at varying distances from the ground center of the explosion in Hiroshima, Japan, on August 6, 1945. An analysis has been made of the clinical histories of 5,136 injured persons and interviews with 1,207 uninjured persons exposed to the bomb. These histories and records of interviews were collected by physicians of the Joint Army-Navy Commission which investigated the medical effects of the bomb within a few months after the explosion (1).

Limitations of the Data

It is recognized that no statistical study of the types of injury incurred as a result of the

Mrs. Reynolds is chief of the Statistics Branch, Armed Forces Institute of Pathology, with which she has been associated since 1946. Earlier she was with the Selective Service System, part of the time as adviser to the director. Also with the Institute, Mr. Lynch is chief of the Atomic Unit, Radiation Injury Pathology Section. He was with the Foreign Liquidation Branch, Department of State, from 1946 to 1947.

atomic bombing in Hiroshima can be fully representative of those actually sustained in that city. Authorities agree that no accurate count of the exact number of dead and injured will ever be possible and that causes of death in the areas of greatest destruction can only be estimated. Since the individuals in our study include only those who survived the disaster and were able to escape from the damaged areas of the city alone or with assistance of others, the distribution and severity of injuries in this group may be expected to differ from estimated causes of immediate death.

The total population of Hiroshima at the time the bomb was dropped and the number of injured survivors have been variously estimated. One such estimate (2) places the population figure at 245,000 with equal numbers—70,000 to 80,000 each—injured and killed, or missing and presumed to be dead. If these figures may be regarded as reasonably accurate, our study comprises a maximum 7.3 percent sample of injured survivors and 1.1 percent of the uninjured—a figure of 98,265 exposed individuals residing in Hiroshima in 1950 was obtained from the Atomic Bomb Casualty Commission's survivor questionnaire, circulated with the Japanese national census of October 1, 1950 (3).

Some bias may exist in our sample, because of the fact that many survivors, both injured

and uninjured, left the city soon after the bombing, and the fact that an unknown number of the injured may have died elsewhere. However, an indication that many of those who fled the city had returned by the time of the interviews is afforded by the fact that the population of Hiroshima had reached 137,000 by November 1, 1945.

A long-range followup of the effects of the detonations on survivors and their descendants may alter some of the data as to actual distance of survivors from the ground center of the explosion. It is possible that the earlier interviewers' estimates of distances at specified locations reported by those interviewed were calculated hurriedly or without the aid of detailed maps which were available to later investigators.

On the other hand, persons interviewed immediately or within a short time after may have given a more nearly accurate description of their positions at the time of the bombing than at subsequent interviews when accounts given by other exposed individuals might have come to be identified as their own experiences. For this reason and also because no similar data based on the interviews by the Joint Army-Navy Commission appear to have been published, it was considered desirable to study the types of injuries in relation to the distances and the type of shelter or lack of shelter afforded the survivors.

A recent semiannual report of the Atomic Bomb Casualty Commission (4) states that "1,009 individuals surviving under 1,000 meters

and 9,191 between 999 and 1,499 meters were located during the Japanese national census in 1950." The Joint Army-Navy Commission sample includes 816 persons who were recorded as being within 1,000 meters from ground center of the explosion, 306 of whom died after admission to hospitals. At the distance of 1,001 through 1,500 meters, the sample shows 1,134 persons, 1,081 of whom were living several weeks to months after the bombing.

General Characteristics of the Sample

The total case records included in this study number 6,343. These include 5,136 injured persons, 384 of whom died in hospitals where their histories were obtained, and 1,207 who were uninjured. All these persons reported that they were within a radius of 13,120 feet from the ground center of the explosion. Not included in the study are a small number of uninjured persons within this distance who were in tunnels or air raid shelters and 229 who were at distances ranging from 13,121 to 16,400 feet from ground center.

The distance, in feet, of the injured and uninjured persons from the ground center of the explosion is shown in table 1. The percentages of uninjured persons increased with increasing distance from ground center as would be expected. The 5,136 injured persons comprise 81 percent of the total.

Four types of protection, or lack of protection, were coded by the original investigating groups and tabulated in relation to the 6,343 persons

Table 1. Injured and uninjured persons in Hiroshima sample study in relation to distance from ground center of explosion

¹ Percentages add to more than 100 since many persons had more than 1 type of injury.

Effects of radiation were encountered in 34 percent of the injured persons.

As would be expected among individuals who survived for several weeks or months, the radiation was more often described as moderate than as severe. We have previously reported that 18 survivors who were reported as outdoors and unshielded within 3,280 feet of ground center had symptoms indicating only moderate radiation sickness (9).

No blast injuries were noted in the persons seen by the Joint Commission physicians, nor, according to the Tokyo Army Medical College (8), were there many survivors with internal

injuries and blood vessel injuries. The possibility of death from central nervous system injury resulting in pulmonary edema and hemorrhage among persons in close proximity to walls or the ground in cases where the blast would strike the surface square on is suggested by Casen, Kistler, and Mankiewicz (10), on the basis of experimental data.

The breakdown of injuries by location (table 3) shows that mechanical injuries occurred in 82 percent of the injured survivors who were inside buildings as compared to 28 percent of those who were outdoors. In contrast, flash burns were reported for 17 percent of the survivors indoors and 80 percent of those outdoors. Radiation effects were noted chiefly among survivors near the ground center, where gamma rays penetrated buildings and where instantaneous deaths from massive radiation may have occurred among persons unprotected by buildings. This may account for the higher percentage of radiation injury among survivors indoors than among those who were outdoors.

The incidence of injuries among injured survivors at different distances from ground center is considered with respect to type of protection

Table 5. Types of single and multiple injuries of 5,136 injured persons

¹ Less than 0.5 percent.

or lack of protection in table 4 and for the percentages outdoors and indoors in figure 1. Radiation injury was found generally unrelated to type of protection, and there was rapid fall-off from the first distance zone outward.

Mechanical injuries were definitely related to the amount of protection afforded. Whereas no more than 28 percent of the survivors who were outdoors and unshielded in any distance zone had such injuries, the percentages with mechanical injuries who were indoors in heavy buildings ranged from 80 to 88 percent. Of interest also are the statistically significant higher percentages of mechanical injuries among persons injured outdoors in each zone who were presumably "shielded" than among those outdoors and unshielded.

The highest incidence of burns occurred in the second distance zone and beyond. Forty-

eight percent of all the injured survivors at 3,281-6,560 feet and from this zone outward had burns, as compared with 28 percent of those nearest ground center. (Burns occurred in only 17 percent of the victims at the 9,841 to 13,120 feet distance.) However, 76 to 91 percent of the injured survivors outdoors and unshielded in each distance zone incurred flash burns. Any form of protection decreased the percentages with burns.

A breakdown of the injuries into single and multiple types revealed that while two-thirds of the injured survivors had only 1 form of injury, this was not true of those within 3,280 feet of ground center, where 67 percent had multiple injuries. The types of injuries, alone and in combination, are presented in table 5. Here, by addition of the percentages, it is evident that 87 percent who were within the first

3,280 feet had radiation, but it was the sole injury for only 22 percent. The most frequent combination at this distance was radiation with mechanical injury,—in 42 percent. Many such patients who received therapy were treated for their mechanical injuries only, since the effects of radiation were not immediately manifest. The influence of various kinds of protection or the lack of protection upon the types of injuries sustained is demonstrated in table 6.

Physicians of the Joint Army-Navy Commission assigned ratings of "severe" or "moderate" to the types of injuries described by the survivors whom they actually interviewed. Similar ratings were not made for the seriously injured persons who died in hospitals. The relative severity of the nonfatal injuries within the first 3,280 feet from ground center, which is of particular interest, is shown in table 7. Symptoms indicating severe radiation occurred in 57 percent of the 510 survivors not fatally injured in this zone, and in 66 percent of those who were outdoors and presumably shielded by walls or other objects. Severe radiation among such survivors in Japanese-type buildings was approximately the same as for those outdoors

and shielded, 64 and 66 percent, respectively. Thirty-eight percent of those in heavy buildings also had severe radiation injury.

Mechanical injuries which were considered severe occurred with approximately equal relative frequency in Japanese-type and in heavy buildings in this first zone.

Mechanical injuries were considered as the most severe type of injury sustained by 1 of the 2,826 persons who had this type of injury. As shown in table 8, the severe mechanical injuries in each distance zone increased with increasing protection and were incurred in approximately one-half to two-thirds of the injured persons who were indoors in buildings, either light or heavy construction.

Summary

Data pertaining to 6,343 survivors (5,136 injured and 1,207 uninjured) of the atomic explosion in Hiroshima on August 6, 1945, analyzed with respect to the incidence of mechanical and radiation injuries and flash burns in relation to distance from ground center and type of protection. The data were based

¹ This table omits the records of 85 autopsied persons since the severity of injury was not recorded by the physicians.

histories and interviews obtained by physicians of the Joint Army-Navy Commission which investigated the medical effects of the atomic bombs in Japan within a few months after the explosions. Pertinent observations are these:

All the exposed persons were within 13,120 feet from ground center of the explosion; 816 were within 3,280 feet; 2,844, from this distance through 6,560 feet; 2,122, from 6,561-9,840 feet; and 561, from 9,841 through 13,120 feet. These were survivors who were able to escape from the area of greatest damage either alone or with a minimum of assistance.

Forty-two percent of the exposed persons were reported as being out of doors at the time of the explosion, and 2,040, or 76 percent, of these were presumably not shielded and so were exposed to the full effects of the explosion.

The majority (3,249) of the 3,653 persons who were reportedly indoors were in buildings of light or Japanese-type construction, and 404 were in buildings of heavy construction.

The percentages of persons who were uninjured increased with increasing distance from ground center. Only 47 of the 1,207 uninjured persons interviewed stated that they were in heavy buildings at the time of the explosion.

Mechanical injuries (lacerations and contusions) were by far the most common type of injury, occurring in 58 percent of the injured, 82 percent of those who were indoors, and 28 percent of those outdoors.

Burns (flash burns in 2,311 and/or flash and flame burns in 11 instances) occurred in 45 percent of the injured survivors; in 17 percent of those indoors as compared to 80 percent outdoors.

Radiation injury, recorded for 34 percent of the injured survivors, occurred chiefly among those who were within 6,560 feet of ground center. The overall percentages of those indoors and outdoors with radiation effects were 39 and 27, respectively.

Although two-thirds of the injured survivors had only 1 type of injury, the same fraction of those within 3,280 feet of ground center had multiple injuries. Radiation was by far the most common injury in this first distance zone.

When the type of protection or lack of protection was considered, it appeared that mechanical injuries were noted more frequently among survivors in buildings than among those who were outdoors, and significantly more often in the relatively few survivors who had been in heavy buildings than among the large number who were in the Japanese-type structures. At a distance within 3,280 feet, 63 percent of the injured persons had mechanical injuries, in conjunction with radiation, burns, or a combination of both in 55 percent. Beyond this distance, the majority of those with mechanical injuries had no other type of injury.

Mechanical injuries classified as the most severe of the injuries sustained were noted more often for survivors in buildings and those outdoors who were shielded to some extent than for those who were entirely unprotected from the effects of the explosion.

FDA Tolerances for Food Crop Pesticides

Procedural regulations issued by the Food and Drug Administration, Department of Health, Education, and Welfare, under the new pesticide amendment to the Federal Food, Drug, and Cosmetic Act went into effect March 6, 1955.

Under the new law, which becomes fully effective July 22, 1955, one year following its enactment, unless extended, food shipments bearing residues of pesticide chemicals in excess of established tolerances will be contraband and subject to seizure as adulterates.

Protection of the public under the law with a minimum of legislation is the aim of the Food and Drug Administration, hence, regulations establishing procedures for determining safe tolerances for pesticide chemicals were published in the *Federal Register*, February 4, 1955, pp. 770-771. However, petitions from chemical manufacturers have been processed according to the terms of tentative regulations published October 20, 1954, and the final regulations will not affect the petitions so processed. Any action taken in compliance with the tentative regulations will be regarded as complying with the law.

The final form of the procedural regulations differs from the tentative regulations principally in the following particulars:

1. A time limit of 15 days is established within which FDA must notify a petitioner of acceptance or nonacceptance of his petition.
2. Rewording makes it clear that a firm need submit a set of toxicity data to FDA only once.
3. An incomplete petition may be filed if the petitioner insists upon it.
4. A petition may be filed before a sample requested by FDA has been furnished.
5. Rewording provides a more definite time limit for consideration of a petition or request by an advisory committee.
6. The fee provisions of the regulation are changed to result in a more equitable assessment of the costs of the service. (The total cost of the service to the pesticide industry is now estimated to be slightly less than the original estimate.)

Regulations fixing tolerances for 28 pesticides that were in common use prior to the passage of the new law are still being reviewed by the Food and Drug Administration.

A Reappraisal of Tuberculosis in Florida

By CLARENCE M. SHARP, M.D., SIMON D. DOFF, M.D., EVERETT H. WILLIAMS, Jr., M.S.,
and ROBERT M. THORNER, M.B.A.

IN RECENT YEARS the tuberculosis mortality rate in Florida has diminished rapidly, declining from 17.9 per 100,000 population in 1951 to 16.9 in 1952 and to a low of 9.7 in 1953. The 1953 rate is substantially below the national rate of 12.5 as estimated from the 10-percent sample of death certificates filed with the National Office of Vital Statistics, Public Health Service (1). Only 303 deaths from tuberculosis among Florida residents were recorded during 1953, and for the first time in the history of death statistics in Florida, tuberculosis was not among the 10 leading causes of death.

It is unfortunate that mortality statistics provide the most frequently used measure of disease problems. They indicate poorly the trend of the incidence and prevalence of infectious chronic diseases such as tuberculosis because of the time lag between infection and death. Mortality statistics alone, as an indication of the magnitude and trend of the tuberculosis problem, are especially unsatisfactory, since improved therapeutic techniques have decreased the proportion of tuberculosis cases terminating in death. However, the rapid decline in mortality and the impending reduction in funds

available for tuberculosis control indicated a reappraisal of the tuberculosis problem and the present methods of X-ray case finding in Florida.

For this reappraisal, statistics collected from the 1953 X-ray screening in Florida were analyzed to develop an estimate of the prevalence of undetected cases in the general population.

An estimate of the number of undetected cases, when used with statistics on known cases derived from the tuberculosis case register, offers a much more satisfactory basis for planning a tuberculosis control program than does the use of mortality statistics alone. Estimates of prevalence made on an annual basis over a period of years will also indicate the trend of the tuberculosis problem more satisfactorily than will mortality figures.

These statistics of known cases and estimated undetected cases offer a good basis for the appropriation of tuberculosis control funds by State and local governments for use in planning hospital facilities and nursing services, for the operation of X-ray case-finding programs, and for the activities of the tuberculosis association.

During 1953, State and local health units in Florida made 70-mm. X-ray films of 382,304 persons. Of these films, 8,882 were interpreted as showing some type of pathology. A total of 4,448 were interpreted as indicative of tuberculosis (table 1).

Followup films were made on 2,762 patients showing signs of definite or suspected tuberculosis. A definite diagnosis of tuberculosis

Dr. Sharp is director of the bureau of tuberculosis control of the Florida State Board of Health. Dr. Doff is director of the board's division of heart disease control; Mr. Williams is director of vital statistics; and Mr. Thorner is chief statistician.

t previously known to the State board of health was established in 497 cases, yielding a new case rate of 130 per 100,000 persons screened on the original 70-mm. X-rays. Since the followup of the original screenings is only 62 percent complete, the actual rate probably much higher. Hospitalization was recommended for 191 patients.

the X-ray Screening Survey

Included in the 70-mm. X-rays were 148,240 exposures made for "mass screenings," principally by mobile units of the State board of health. As more complete information concerning both the persons X-rayed and the results of followup was available for this group, detailed analysis was made from these data. The age, race, and sex distribution of this group is compared to the general population and found to differ significantly. However, on the basis of available information, adjustments were made for these factors and statistical inferences were drawn regarding the prevalence of undetected tuberculosis in Florida. The methodology and results of this analysis are presented in this paper.

The 29 Florida counties surveyed (map) are not randomly distributed throughout the State, but are concentrated in western and south-

western Florida. Three universities located in counties not shaded on the map were also included in the survey. Since the survey was not intended primarily as a statistical study, no attempt was made to insure a random sample. The survey was made to find and bring to treatment cases of tuberculosis, and the statistics available represent a byproduct.

Counties were selected for screening on the basis of the time elapsed since a previous survey of that county. The mean elapsed time between the last survey of the counties in the study and the 1953 survey was 24.7 months, ranging from 11 months to 71 months. The length of elapsed time between surveys is undoubtedly a factor in the number of tuberculosis cases detected. A correlation between the time elapsed and the size of the new case rate in the counties surveyed showed a positive coefficient of $r=.41$. This correlation is significant statistically at the 5-percent level. Since the counties not included in the survey had been screened more recently than those included, some upward bias has been introduced into the prevalence estimate by this factor.

This bias has probably been more than offset by the fact that the counties surveyed are predominantly rural, and the counties containing Florida's largest cities are not in the area surveyed. Since tuberculosis case rates are generally higher in large cities, the geographic distribution of the counties included would tend to have a downward influence on the prevalence estimate (2).

Another factor exerting a downward bias upon the estimate of prevalence is the inherent assumption that nonrespondents to the survey would show a proportion of tuberculosis similar to that of the screened population. There is some indication that a higher proportion of the population which did not voluntarily respond to the survey would show signs of definite or suspected tuberculosis (3).

The methodology of the survey was typical of mass X-ray screenings of the general population. Advance publicity was given to the arrival of the survey unit. The X-ray team set up shop in a prominent location and photographed all persons 15 years of age or older volunteering.

These 70-mm. films were then read, chiefly

¹ Excludes unsatisfactory films.

² Followup of 70-mm. films with impressions of definite and suspected tuberculosis.

As a result of these followup films, 187 new tuberculosis cases were definitely diagnosed, yielding an unadjusted case rate of 126.1 per 100,000 adults successfully X-rayed by the original 70-mm. films.

Since information regarding the age, race, and sex was collected at the time the survey X-rays were taken, it was felt that a good estimate of the number of undetected cases of tuberculosis could be made by use of these data.

The race, sex, and age distributions of the 145,267 negative X-rays were estimated from this sample, and the distribution of the films with pathological findings was added to this to derive an estimate of the distribution of all of the 70-mm. films taken.

Since 1953 was fairly close to the census year of 1950, information concerning the race and sex distribution of the population of Florida in 1950 was used as a standard against which to

judge the representativeness of the surveyed population. The adult population of Florida was distributed on a percentage basis by age, race, and sex, and these percentages were used as a theoretical set of frequencies for comparison with the survey group (table 2).

The persons of known age, race, and sex in the survey group were redistributed according to the theoretical frequencies, and a chi square test made. The survey group was found to fit the theoretical distributions poorly, chiefly as a result of the large number of university stu-

dents included, and was judged not to be representative of the total Florida population.

To compensate for the poor correspondence of the survey population to the general population, age-specific rates were computed and used to derive an estimate of the number of undetected cases in Florida.

Rates were developed for specific population groups based on a cross tabulation by age, race, and sex of the 187 new cases, and the corresponding number of persons in each age, race, and sex group of the surveyed population. The estimated adult population of Florida as of July 1, 1953, was prorated according to the age, race, and sex distribution of the 1950 census. The age-specific rates were then applied to each population group to derive an estimate of undetected cases in 1953.

This procedure introduces many possibilities for error. The number of cases in each age bracket is small, and the rates correspondingly irregular. The age distribution of the population has undoubtedly changed since 1950, and the projected population also must vary from the actual to some degree. However, it is believed that the method is reasonably accurate and is considerably better than an estimate based on the unadjusted case rate.

One additional adjustment was believed necessary to derive a prevalence of undetected cases in 1953: an adjustment for incomplete followup of the definite and suspected cases detected on the 70-mm. films.

The film impression results, percent followup by race, sex, and age, and new cases found appear in tables 3-5. No significant difference in percent followed (at the 5-percent level) could be found for the two most divergent age groups, or by race (table 4). It was therefore decided that the overall followup percentage (75.2) could be used as an adjusting factor if it were assumed that a similar proportion of the cases lost to followup would have been definite tuberculosis cases. The adjusted figure for undetected cases in 1953 is 4,856, and the rate 211.1 per 100,000 adult population.

To this figure may be added the 11,608 known cases of active, questionably active, and inactive pulmonary tuberculosis under supervision by local health departments in 1953, yielding a prevalence estimate of 16,464 known and undetected cases.

In contrast to the small number of deaths, 303, these figures indicate that tuberculosis remains a major health problem in Florida.

Table 5. Activity and stage of new cases found, by race, sex, and age, mass X-ray screenings, Florida, 1953

¹ Rate per 100,000 satisfactory 70-mm. films.

Administrative Uses

Administratively, several important facts became apparent as a result of the detailed analysis. While the case rate increased considerably with age (table 5), the proportion of the population surveyed became progressively smaller with age (table 3). Case rates were higher for males than for females (table 5), but a relatively constant proportion of each sex group was surveyed. Evidently, case-finding efforts will yield greater returns if a greater proportion of older persons and males can be screened.

The largest proportion of cases found (87.2 percent) were in the minimal or moderately advanced stages, indicating that the mass screening technique is successful in finding cases at a stage when treatment of active cases or supervision of questionably active cases can be most successfully undertaken.

The distribution of new cases by activity is based chiefly on the reading of the 14" x 17" followup films and only in part on clinical study. The proportion of active cases decreased progressively with age, and the proportion of cases with activity undetermined tended to increase. This has probably resulted from the difficulty of making a diagnosis from 14" x 17" chest X-ray films in older persons who are more likely to have calcification, fibrosis, and caseation, whereas the younger patients are more apt to have exudative lesions and present less difficulty in determining activity.

Future Plans

The productivity of X-ray screening will, of course, diminish as the prevalence of tuberculosis is reduced, and the cost per case found will increase correspondingly. It is difficult to assess at what point the yield of the X-ray technique does not justify the expenditure.

In Florida, the 1953 X-ray screenings yielded 497 new cases. There are no figures available showing how many additional cases resulted from the followup of contacts of these infected persons, but this number is believed to be substantial. It would seem that this method of case finding is still sufficiently productive in Florida to warrant its continuance.

As the prevalence of tuberculosis is further reduced, the X-ray screening program will be directed toward those areas and age, race, and sex groups which will yield the greatest number of cases as indicated by the present general surveys.

The State of the Nation's

THE
NATION'S
HEALTH
REPORT
1954

Excerpted reports from the 53d Annual Conference of the Surgeon General of the Public Health Service and the Chief of the Children's Bureau with the Association of State and Territorial Health Officers and with State Hospital and Mental Health Authorities, December 6-10, 1954, Washington, D. C.

Health Action Programs To Meet The Needs of Today

1 **By Oveta Culp Hobby**
Secretary of
Health, Education, and Welfare

These annual meetings give us in the Department of Health, Education, and Welfare an opportunity to find the ways in which the local, State, and Federal governments can best work together for the better health of the American people.

During the coming year we in the Department are going to place primary emphasis on health and on the means through which we may move toward its improvement throughout the Nation.

In today's world the prospect of better health and of longer, happier lives for the American people now is not a distant dream. This Administration has set itself the task of narrowing the gap between what is possible and what is actual.

President Eisenhower has left no doubt regarding the vigor with which a health program will be pushed. As the President said in his speech at the Alfred E. Smith Foundation in October:

"The start now made is only a first beginning on a vast human enterprise—the health of our Nation. This is a task for the individual citi-

zen, the city, the county, the State, and finally, the Federal Government. We Americans have accomplished near miracles in material things. But we are years behind our potential achievement in the availability and adequacy of health services. That deficiency we shall correct.

"But I repeat, the task does not belong exclusively or even primarily to the Congress and the Government. It belongs to each of us and to the communities in which we live. The inadequacy will be fully remedied only as each of us performs his full duty as an American citizen, certain that in so doing he is not only relieving distress but making a more durable contribution to the Republic."

Sound legislation is one of the requisites for action. The last Congress, as you are aware, enacted two important measures directed toward today's health problems. These broadened and extended the Hospital Survey and Construction Program and substantially expanded the Federal-State program to rehabilitate the handicapped.

As a result, you—and your colleagues in communities throughout the Nation—are already, or will shortly, have a part in planning the construction of badly needed chronic disease hospitals, nursing homes, rehabilitation centers, and diagnostic and treatment clinics. More disabled people will be returned to active, useful lives. There will be more facilities and more services for the care of older people and those chronically ill.

These are forward steps. They are in keeping with our efforts to see that health programs and activities are designed to meet today's needs rather than yesterday's crisis or tomorrow's imponderables.

One of our important objectives has been to encourage the growth and improvement of voluntary health insurance so that more people can be protected against the costs of illness. To this end the President has proposed a system of voluntary health reinsurance.

In Exploratory Stages

Many of the health problems which need planning and action are as yet in the exploratory or preliminary stages. I would like, however, to mention some of the problems.

Many of you here have a deep interest, for example, in the problems of air pollution and of water pollution. Some States have already undertaken, in cooperation with local communities, remedial efforts. The President has expressed his deep concern about air and water pollution problems. Certainly there is a great need for expanded activity here, particularly in the way of research and field investigations.

Juvenile Delinquency

Another grave national problem is juvenile delinquency. The Department has been studying methods by which the Federal Government can assist States and local communities in meeting this serious social problem, with its important health implications.

New concepts are emerging which point to ways health departments can help prevent delinquency. Mental health principles are being increasingly employed in health and treatment centers serving parents and children. Certainly those of you who are administering mental health programs have a great deal to contribute in the battle against delinquency.

To combat juvenile delinquency, the Congress made a supplemental appropriation of \$75,000 to the Children's Bureau. This appropriation will enable the Bureau to aid States, local communities, and other groups to plan, coordinate and improve the services they provide for delinquent children.

The Field of Civil Defense

This Department has recently received by delegation from the Federal Civil Defense Administration some very serious responsibilities in the field of civil defense. In approving this delegation, the President has again indicated the importance with which he regards this program in planning for national welfare and security.

Many of you have already done considerable work in planning for casualties in the event of local disaster. We must give increasing attention to the problem of maintaining living conditions as close to normal as possible in the face of the confusion and dislocation which would follow such a disaster. As a result of the recent

delegation of authority, the Department can now work with you in developing a coordinated national approach.

In connection with this activity, I should like to make special note of the Public Health Service's plans for substantial expansion of the Commissioned Reserve. The principal reason for this, of course, is to provide a corps of trained public health workers for service in national emergencies. Its immediate goal is the commissioning of an additional 2,000 reserve officers by June 30, 1955.

Another recent significant event has been the congressional transfer of the health and hospital services for the Indian people from the Bureau of Indian Affairs to the Public Health Service.

State-Federal Relations

The Department is going to need your help in the solution of this complex problem. Effective use of our existing local-State-Federal machinery for preventive services and disease control will give us our best chance for success.

It is through the established pattern of combined local, State, and Federal action on health problems that we can reach our mutual goals of a stronger and healthier America. The philosophy of Federal-State relations held by this Administration, and by the Department, coincides closely with your own. Some of our basic beliefs parallel those embodied in the proceedings of these conferences over the years.

Let me conclude by restating a few. We believe:

That the States and the Federal Government are interdependent in the fight against disease and disability.

That the Nation as a whole must share responsibility for those State and local public health services of national or interstate significance.

That when more effective methods of combating health problems are developed, assistance should be made available for their nationwide application.

That all this should be done with a maximum of State and local initiative, decisions, and State responsibility—and with a minimum of Federal control.

On these principles, the work of the Department has gone forward. With this philosophy, I am convinced, we can continue to meet today's health needs, and tomorrow's.

Breaking the Trail For New Public Health Advances

2

By Leonard A. Scheele, M.D.
Surgeon General of the
Public Health Service

In this meeting, you and I are carrying out a statutory responsibility first placed upon the Nation's Federal and State health agencies more than half a century ago. The State and Territorial health officers, together with the State hospital and mental health authorities, comprise the largest group of official advisers to the Public Health Service.

As your chairman, I wish to place before you a few of the important events that have occurred in the Public Health Service since we last met. This I propose to do first, and then to discuss with you the orientation of public health to deal more effectively with the major health problems of today.

Facilities Construction and Rehabilitation

I need not elaborate on the provisions of the Medical Facilities Survey and Construction Act of 1954. The Public Health Service has been meeting with State and Territorial hospital authorities and with representatives of the many other groups involved in the program. The Federal Hospital Advisory Council has met twice to discuss and pass upon regulations, to be issued officially on or before January 1, 1955. A supplemental appropriation, providing \$2 million for State surveys and \$21 million for construction grants, has been passed.

With publication of the regulations, the way will be clear for the States to complete their surveys and develop their plans for construction in the neglected fields of chronic disease facilities, diagnostic treatment facilities, nursing homes, and rehabilitation facilities. We look forward to the development of a program as successful in improving the Nation's health as the original Hill-Burton program. We all have a fine opportunity to help fill important gaps in the Nation's physical resources for health, specifically in resources for care of the long-term patient.

Vocational Rehabilitation

The expanded rehabilitation program administered by the Office of Vocational Rehabilitation offers another opportunity for progress. I had the privilege recently of addressing the National Rehabilitation Association at its annual meeting. The association is one of the major voluntary agencies in its field and counts in its membership State and Territorial directors of vocational rehabilitation and services to the blind. It seemed to me significant and prophetic of future cooperation that they should invite a health officer to deliver their keynote address.

I urged your counterparts in the field of rehabilitation to seek the cooperation of their official health agencies. So I urge you to increase your cooperation with State directors of rehabilitation and services to the blind. As staunch allies, our State health and rehabilitation agencies have it in their power to bring about real advances in care of the handicapped and in control of chronic diseases and care of the aged.

Indian Health Services

The transfer of hospital and health facilities for American Indians to the Public Health Service was accomplished with the approval on August 5, 1954, of Public Law 568, 83d Congress.

Besides the obligation to develop and operate an adequate hospital and medical care program for the Indians, the Service is challenged to apply the public health methods which we know

can greatly reduce Indian mortality and morbidity owing to preventable diseases. We expect to encounter problems like those with which our health missions are dealing in foreign countries. Indian health problems are often the problems of people who retain their primitive cultures and who have never known high standards of living or high quality health services.

Just as the Public Health Service and the States have worked together in helping to solve similar problems overseas, we will also be calling on you for advice and active support in the Indian health program. This includes your active help in recruiting personnel. We hope that State and local agencies will be able increasingly to provide a larger share of direct health services to Indians. We plan to increase emphasis on preventive services, on early case finding and treatment, and on improved medical care in the ambulatory clinics and hospitals.

Water Resources and Pollution

The Nation's problem of water resources is receiving intensive study at the highest policy levels of Government. The Public Health Service is participating actively in the work of the President's Cabinet Committee on Water Resources Policy as well as in the work of the new Interagency Committee on Water Resources.

Water pollution control is a vital factor in water resources development. Water shortages can sometimes be met through construction of dams to store water for use as needed. The solution, however, must be found in the preservation of water quality through pollution control. This permits repeated use of water as streams flow from city to city and from industry to industry.

It is always easier to get public and official support for the development of new sources of water supply and for water treatment facilities than for treatment of sewage and wastes. No one wants to worry about unglamorous waste treatment so long as sewers carry away the wastes.

"Out of sight, out of mind" is a dangerous attitude toward sewage and wastes. I hope that you will use your influence to disabuse the public and State and local government officials of this attitude. They must be made aware of the

critical need for waste treatment works. Water works have advantages today which are not provided sewage treatment works. A real need is to develop better methods for financing sewage treatment as an integral part of the community's total water service.

In Civil Defense

The Federal Civil Defense Administration has delegated specific authorities to the Department of Health, Education, and Welfare. Those for which the Public Health Service is responsible include: (a) research, primarily in the fields of biological and chemical defense; (b) development of a national program of technical guidance to the States and direction of Federal activities for the emergency restoration of community public health services; and (c) provision of Reserve Corps officers for emergency service in heavily damaged areas.

The National Institutes of Health, the Communicable Disease Center, and the Robert A. Taft Sanitary Engineering Center are working on projects in cooperation with the Armed Forces, the Atomic Energy Commission, and the FCDA. The Office of Health Emergency Planning in the Office of the Surgeon General remains the coordinating unit in the Public Health Service and is our primary liaison with these key agencies.

An expanded defense training program for key personnel of the Public Health Service is now under way. A main purpose is to develop new materials and instructional activities for State and local health personnel. The Service will be concerned not only with technical problems but also with administrative methods for utilizing all public health resources in an emergency.

Commissioned Reserve Corps

Perhaps the most challenging of our new defense responsibilities is the development of a more adequate Commissioned Reserve Corps in the Service. World War II proved that to be effective a Commissioned Reserve should be recruited in peacetime and adequately trained for duty in emergencies. The plan is to take those steps now and thus avert conditions which

were unsatisfactory to all concerned during the last war.

Our aim is to augment—not to deplete—the available supply of personnel for duty in public health activities and to assure their mobility. In developing the Commissioned Reserve we will work out with you plans for the most effective training and utilization of existing health personnel. At the same time we will recruit actively outside State and local public health staffs.

We will use every available resource to train reserve officers in the health problems associated with atomic, biological, and chemical warfare, and other emergency health problems. We do not expect to call officers in the emergency reserve to active duty without their consent, except in the face of a clear and present danger, publicly recognized.

It is to the self interest of every health officer and his staff to promote the development of the Commissioned Reserve.

The Goals of Public Health

The fundamental goals of public health have not changed with the changing years and the changing world. Our professional forefathers set those goals in broad terms that are as relevant to our times as to theirs.

Shattuck in 1850 wrote:

"The conditions of perfect health, either public or personal, are seldom or never attained, though attainable . . . The average length of human life may be very much extended and its physical power greatly augmented . . . A vast amount of unnecessarily impaired health and physical debility exists among those not actually confined by sickness . . . These preventable evils require an enormous expenditure and loss of money and impose upon the people unnumbered and immeasurable calamities, pecuniary, social, physical, mental, and moral, which might be avoided . . . Means exist, within our reach, for their mitigation or removal . . . Measures for prevention will effect infinitely more than remedies for the cure of disease."

Please note that no particular groups of diseases, no special population group is singled out as the proper objective of public health action. There is no narrow definition of the means

by which the goals of personal and public health shall be attained, save an affirmation of the universal truth that prevention is more effective than cure. The goal is not merely to extend life but to augment its power. The full physical, mental, economic, and social impact of ill health is recognized as the proper target of public health action; and prevention includes "mitigation or removal."

These are the problems and goals of public health today. The fact that the major causes of death and ill health have changed does not remit one single clause in the public health charter of responsibility.

There is a tendency to restrict these problems and goals to a narrow vision of conquering specific disease entities by specific techniques. We are challenged, therefore, to throw off our blinders and see. As the specific problems have changed, so our approaches to, and methods for, their solution must change also. Even the traditional fields, sanitation and communicable disease control, demand new approaches and methods.

Air Pollution

I would like to give you one illustration of the lag in attacking new problems in these old fields.

Air pollution is a chronic, massive problem for virtually every large city in the country. In the past 6 years, the public concern about air pollution has reached fever pitch in some urban areas.

There has been a notable lack of interest and action in State and municipal health agencies and in some of the Federal services. When we mention Pittsburgh, St. Louis, New York City, and Los Angeles, we have just about called the roll of metropolitan areas which have had any major control effort leveled at their problems of air pollution.

No one has yet developed fully effective control measures for all types of air pollution, especially for the invisible fumes and gases discharged into the general atmosphere.

We do not have epidemiological data to compare a generation's experience in exposed and control populations. But there is a body of information—engineering, chemical, meteoro-

logical, and medical—which confirms the public concern and which would provide a beginning measure of control, if applied. However, there is a basic need for intensified research by all groups concerned: industry, private laboratories, communities, States, and Federal agencies.

We also need intensive scientific study of many other unsolved problems in environmental health and in communicable disease control. Such studies absorb a significant proportion of the Nation's total medical and public health research expenditure; and they will eventually yield results that may radically change our approaches and methods in these traditional fields. But real improvements can be made now, by applying what is known today. We cannot deal with the chemical and viral threats to health by a "swivel-chair" approach, nor by chief reliance on methods learned even 20 years ago.

There must be a critical appraisal of our methods in all fields and a shift of our public health efforts away from the obsolete activities. Even more important, we must orient our young professional staffs in the new problems public health faces. If we do not make these changes, I fear that public health departments will not play the significant role which should be theirs in helping the Nation to lift the physical, mental, social, and financial burden of long-term illness. New State and local agencies will continue to be created, outside established health departments, to deal with this transcending health problem. The fragmentation of health services will continue, while many health departments, with fine records of past accomplishment, will be left at the starting post.

Long-Term Illness

Long-term illness cannot be defined nor successfully attacked in terms of specific disease entities and their specific control. The roots of long-term illness are in a vast multiplicity of causes, some of which are known, and many of which are unknown. Long-term illness reaches into every segment of individual and community life.

Last spring the Commission on Chronic Illness called a conference on care of the long-term patient. The title of the conference was

no idle choice; it places the focus where all future effort in the control of chronic diseases must be placed—on the patient. I commend the recommendations and proceedings of that conference to your earnest study.

We cannot fail to be impressed by the growing body of medical knowledge and professional skills ready for application to the problems of the long-term patient, as well as with the increasing number of community experiments with new types of service for the chronically ill and the handicapped. However, our public health methods for tapping these resources and applying the new skills are, on the whole, deficient.

This leads me to suggest a refocusing of public health attention—on the individual patient. If we are to maintain our front-rank position in the maintenance of the Nation's health, we must work more effectively with medical practitioners and with a wider range of voluntary and official agencies concerned with prolonged illness. All of us must become better specialists in dealing with people, and more expert in the organization of resources for the care of the long-term patient.

Coordination of Services

Our experience in attempts to control specific diseases by means of specific techniques has clearly revealed many organization problems. It has shown us that the major barrier to good results is the lack of coordination of public health, medical, and related services in the community. We need much more research and more pilot projects in this vital area. Meantime, there are encouraging signs of a growing interest among health departments in better organization of their own resources.

Several State and large city health departments are engaged in studies or practical application of methods related to the coordination of services.

The Public Health Service has recently reorganized its Bureau of State Services and has established an Interbureau Chronic Disease Study Committee. Both actions have the purpose of integrating our operations along functional lines, and of affording better coordination with related activities in the Department

of Health, Education, and Welfare, the States, and voluntary agencies.

The New York City Health Department has recently undertaken a significant study in cooperation with the Service. The first phase of the study is to determine the extent of referral and coordination between municipal health services and the services provided by industries, organized groups such as unions, and voluntary agencies. We are confident that the findings will give clues to better methods for coordinating community health services, but we need a great deal more experience than our current efforts can provide.

Although the Nation has not gone as far as it will go in the coordination of medical and hospital services, the past 10 years have seen rapid progress in this direction. The teaching hospital and the medical center are being turned to increasingly as sources for consultation and continuing education programs for the medical and related professions in the major health problems of the day.

Personnel Problems

We have made too little progress in the recruitment of public health personnel, especially of physicians. What are the barriers? Public Health Service studies of the engineering profession indicate that low economic reward is not the sole, nor even the determining, barrier to entering sanitary engineering. Recruitment practices proved to be poorly timed, and the information supplied to engineering students proved inadequate.

Can we do something about comparable problems in medical schools, and even in their seedbeds—the colleges and high schools? The pre-medical and medical curriculums could be enriched to show the students that public health and administrative medicine have attractions comparable with those of the clinical specialties. State health officers are in excellent position to influence educational authorities in their States in this direction.

Need for Special Training

The Nation's medical schools are turning out a superior product in all departments. The new

medical graduate has a far better concept of the role of the general practitioner, and of the significance of psychiatry and preventive medicine than his counterpart of 15 or 20 years ago. The teaching of cancer and of cardiovascular and mental diseases also has been expanded during the past 5 or 6 years. Very few medical students in the future will reach their internships without up-to-date instruction in these important fields. In more medical schools than ever before, modern concepts of preventive medicine and environmental health are being taught as important elements of the undergraduate curriculum.

Nevertheless, the supply of physicians available for public health and medical administrative work is meager, and the majority of graduates in all the health professions still require specialized training to do a competent job in our health departments. The cutbacks in recent years in the training programs of State health departments are therefore most disturbing. Our State and local officials and legislative bodies must be made aware of the needs for special training of men and women after employment in public health.

Professional public health workers of today must be more than craftsmen skilled in the performance of specific techniques. They must be creative thinkers—problem solvers in a much larger universe of problems than they have hitherto accepted as their responsibility. They must be masters of a body of knowledge in relationships and resources, upon which they can base sound proposals for dealing with each new situation involving the health of a community and its individual citizens.

I leave you with the same challenge that has faced us each of the past 6 years I have spoken to you from this platform. It is a challenge of adjustment and adaptation to changing needs, a challenge that cannot be fully met over a lifetime.

We are beginning to see in clearer outline the total problem of prolonged disability. Means for its prevention and reduction are increasing in number and effectiveness. Our next steps should be toward a better orientation of our thought, our personnel, and our services for the application of the new knowledge—present and

to come. We must not be complacent because of our low total death rate. We must remember that with the prolongation of many more lives into older age brackets many more people are suffering the chronic and crippling illnesses of older age. These are our challenge.

Child Health Problems: Juvenile Delinquency; Black Market in Babies

3

By Martha M. Eliot, M.D., Sc.D.
Chief of the
Children's Bureau

The major development of 1954 in the Children's Bureau is the creation of a new division to deal with the problems of juvenile delinquency.

The Division of Juvenile Delinquency Services will provide technical aid to States and local communities. The new division will work closely with the Bureau's Division of Health Services and expects to prepare material on the role of health departments in the prevention and treatment of juvenile delinquency.

The high point in the Bureau's efforts to deal with the problems of juvenile delinquency was a national conference, June 28-30, attended by police officers, juvenile probation officers, welfare and health workers, educators, churchmen, and others who are professionally engaged in programs on behalf of youth.

During the year a number of publications relating to juvenile delinquency were completed. One of these, "Standards for Specialized Courts Dealing With Children," was prepared in cooperation with the National Probation and Parole Association and the National Council of Juvenile Court Judges.

Other publications included "Police Services for Juveniles" and "Tentative Standards for Training Schools." Still other publications tell citizens about the nature of the problems of juvenile delinquency. Statistical and research studies have also been made.

Black Market in Babies

Another problem of great concern is the so-called black market in babies. By this, we mean the sale of babies for profit to would-be adoptive parents. Health departments can be of major assistance in helping meet this problem.

Most of the babies involved are born to young unmarried women. Approximately 146,500 babies are born to unmarried mothers each year. Almost one-fourth of these mothers are only 17 years or younger. The black market operators take advantage of these girls at a time of deep emotional stress.

In some cities the practice of agreeing to give up the baby in advance of birth in order to have the medical bills paid has resulted in a black market that is very lucrative to the operators.

The Bureau has employed a specialist to develop plans for enlisting the cooperation of legal, medical, social work, and law enforcement groups in an effort to improve and extend social services and medical and hospital care for unmarried mothers and to eliminate or reduce unprotected placement of children in adoptive homes.

We must also concern ourselves with babies placed in families not related to the baby by persons who have every desire to help but who cannot provide the legal or social protections every adoption should have. Even though no money is exchanged, this type of unprotected placement may be just as bad for the child as one taking place in the black market.

Efforts directed in some of the following ways would of themselves result in the prevention of many unprotected placements:

State health departments can cooperate with welfare departments on the health aspects of the problem and can work with medical societies toward a better appreciation of the importance of good adoption practices.

The local health officer is often in a favorable position to bring together the several public and private agencies that are involved.

Prenatal clinics have much to offer to the care of the pregnant girls.

Public health nurses through their close knowledge of the communities in which they work are in a strategic position to assist girls in getting to social agencies and in working out arrangements for medical and hospital care during confinement.

Mental Retardation

During the past few years a large number of parents of mentally retarded children have organized the National Association for Retarded Children and are doing a great deal to focus public interest on the needs of these children. This group, numbering about 30,000 parents, includes many who are forthright in letting it be known that they have mentally retarded children.

Although we are reexamining an old problem, we are learning that mental retardation is not in itself a single entity but includes a wide range of intellectual ability below an I. Q. of 70 or 80. Most of these children are believed to have a mental capacity that makes at least partial self-support possible to attain.

The Bureau is particularly interested in what can be done to help these children during infancy and the preschool years. This is the period when parents have doubts regarding their child's development and take him to their physician or to a child health clinic for diagnosis.

Far too often the advice is to place the child in an institution even though institutions are so crowded that there is a long waiting period and many will not accept a child until he is 6. A large proportion of these children will develop much better at home. The preschool years are a significant period for the child's development during which the parents need much help.

A program for mentally retarded children should include a special diagnostic center in connection with a pediatric program where the diagnosis can be made and where a plan can be developed for each child at an early age. On

this basis, referrals for institutional care can be made on a much more selective basis than at present.

Most parents would be much better able to care for these children at home, at least in early childhood, if such care were a part of a plan that includes followup visits to the special clinic for supervision, nursery school classes, special classes at regular schools, and social services. Such a program calls for a close working relationship on the part of the health, education, and welfare departments, and the parents of the children.

The Bureau has recently granted funds for a pilot project at the Children's Hospital in Los Angeles. We hope to employ a specialist to study how community services for mentally retarded children can be further developed. The Bureau, the Office of Education, and the National Institute of Mental Health of the Public Health Service will work to press for improvement in many aspects of this community program.

Children of Migrants

Ten States in the east coast migrant stream met here in May 1954 for a conference sponsored by the Public Health Service, the Children's Bureau, the Office of Education, and the Bureau of Public Assistance. The States planned the agenda and during the conference developed concrete plans for action. Public and private groups within the States actively engaged in working with migrants were included.

Since the conference a number of things have happened. United efforts by a number of agencies resulted in a day care center in one Pennsylvania county. Using a special project grant from the Bureau, the Florida State Health Department has employed a coordinator of migrant activities to work in the counties with large migrant populations and to follow the families up the coast to see what they get or do not get in the way of services.

The Department is acting as a clearinghouse for information progress in the 10 States represented at the conference and is soliciting information from each to pass on to the others in the migrant stream.

Nearly 8,000 of the school transfer record

developed during the conference have been requested by the States. This is a small card which the child carries from school to school: it contains brief data on his grade placement and his health record.

The conference referred to your committee on migrants the recommendation that a similar record be developed for health. Another recommendation called for the health officer in each of the 10 States to name a representative to a task force to develop minimum standards for housing and sanitation for transient laborers.

Maternal and Child Health

The gains of the past few years in maternal and child health have been maintained. Definite progress is being made in the prevention of retrolental fibroplasia, an unknown disease a few years ago but now the leading cause of blindness in children.

With the increasing skills we have acquired in saving the lives of premature infants, especially those weighing less than 1,500 grams, the emergence of retrolental fibroplasia as a disease of small premature infants is one of the major obstacles in their care. Some physicians, parents, and others have had misgivings about life-saving efforts which have resulted in a sharp increase in blindness among babies.

There is now strong evidence that excessive oxygen administration is the major cause of retrolental fibroplasia. This evidence comes from clinical observations and laboratory studies, from independent observations, and most recently from a national study.

Study on Retrolental Fibroplasia

A preliminary report (September 1954) of the National Cooperative Study on Retrolental Fibroplasia represents the first 6 months' experience of 75 pediatricians and ophthalmologists in 18 hospitals over the country. Premature infants who weighed 2,500 grams, or less, at birth and who survived 48 hours were assigned to 1 of 2 groups. One group of 68 infants was given oxygen in routine amounts; the other group of 144 infants received curtailed amounts.

The study was set up to test not only the association between the use of oxygen and the incidence of retrolental fibroplasia but the mortality risk involved in the use of curtailed amounts of oxygen.

The preliminary results show no significant difference in the mortality of the two groups of infants receiving different amounts of oxygen. There was, however, a significantly lower incidence of retrolental fibroplasia in the infants whose oxygen was curtailed.

The conclusion drawn from this and other studies is that the use of oxygen should be restricted to amounts which are required for the survival of the infant. Although oxygen requirements of individual infants vary, present recommendations seem to be that no infant be placed in a concentration of oxygen over 40 percent.

This good news gives us every encouragement to increase our programs for prematurely born infants and our efforts to reduce the incidence of premature births and of fetal deaths.

Studies by the Chicago Board of Health emphasize the importance of the first day of life in the survival of infants. More attention to this period, a critical one for many babies, will result in greater reductions in neonatal mortality. This requires application of existing knowledge regarding the causes of death of premature infants as proved by autopsy, better prenatal care, and improved management in pregnancy and labor of mothers who have complications of pregnancy.

Crippled Children's Services

Each of you has a major role in the State crippled children's programs, if not through administration, then through the case-finding, preventive, and followup services in your local health administration and in your maternal and child health programs.

The experiences gained through the crippled children's programs since 1936 provide an invaluable laboratory for the study of medical care administration and of long-term illness. Here are most of the ingredients of prevention and medical and social rehabilitation. Here is a program that has the strong support of public

and voluntary agencies, of private practitioners, of parents, and of the general public.

As we see how the interest in the crippled child increases and how much there is to be done, the methods we use to extend and improve these programs become increasingly important.

I am impressed by the wide varieties among the States in the proportions of the different diagnoses. In one State 38 percent of crippled children receiving physicians' services in 1 year had a diagnosis of hearing impairment. In other States which include this condition, the proportion is as low as 1 percent. The percentage of children under care because of congenital malformations varies from 44 to 6 percent. Yet, there is no reason to believe that the incidence of congenital malformations differs much from State to State.

To a very considerable degree, the crippled children's agencies are dependent on the maternal and child health programs for finding and referring the children with congenital malformations. The largest proportion of children in the programs are those who have congenital malformations of varying types, comprising 21 percent of all the children receiving physicians' services.

Most of these are recognizable early, and, therefore, your public health nurses and child health conferences are a major source of case finding and early referrals. I need hardly tell you how important early case finding is in the provision of medical care and the prevention of disability or its progression.

School health services are another major source of case finding. We have an efficient and rapid means for case finding through audiometry although most States have as yet not been able to include children with hearing impairment in their programs.

For the first few years of the crippled children's programs, virtually all the children receiving care had orthopedic diagnoses. Then, children with rheumatic fever were included, first in one State and then in another until gradually 28 States developed rheumatic fever programs.

Similarly, children with cerebral palsy, epilepsy, congenital heart diseases, hearing impairment, and other conditions have been included in many States. This has come about largely

rough the demonstration technique which public health has employed so successfully..

Artificial Hands for Children

The Bureau has been working with the Army Prosthetic Research Laboratory of the Walter Reed Army Medical Center to see if a lifelike, functional hand comparable to the new artificial hands available for adults could be developed for children.

The first step was to contract for the production of the dies for the hand in 3 sizes: 6 years, 12 years, and adolescence. In view of the expense involved and the many problems to be explored in the use of children's hands, no single group or company could undertake the venture.

Accordingly, last spring the Michigan Crippled Children Commission with a grant of special funds from the Bureau contracted with a prosthesis company for the manufacture of dies for children's hands. An additional grant will make possible the production and delivery of functioning hands during the next fiscal year. Once one or two prosthetics companies are in production, it will then be possible for all crippled children's agencies and for voluntary organizations, hospitals, physicians, and others to order functioning artificial hands for children.

We can then study how the loss of an arm affects physical and emotional growth and development and how children can best utilize a functioning artificial hand.

The number of children receiving care in the crippled children's program is quite small, about 10,000 a year. But there are approximately 1,000,000 with orthopedic handicaps, 675,000 with rheumatic fever, 300,000 with epilepsy, 100,000-500,000 with severe hearing impairment, and many others.

We do not know to what extent all these children are getting care from private and voluntary resources, nor how adequate is the care they are getting, nor how many are going without care. Again and again, the experience in the crippled children's programs has been that when a new clinic opens or a new service starts, large numbers of children in need of care appear.

The success you have had in translating research results into organized community programs, together with the growing concern of civic groups, leads me to believe that we are on the threshold of major new developments that will bring to crippled children everywhere the medical, social, and rehabilitative services they need.

Mental Health Services In a Program Of Public Health

4

By Arthur P. Noyes, M.D.
President of the
American Psychiatric Association

In spite of the striking reduction in certain types of illness through public health measures there remains one group of diseases in which there has been little or no reduction and which now fills approximately as many hospital beds as do all other illnesses combined. This group, as you know, is that of mental diseases.

With the increasing insights which psychiatry has brought both into the more or less serious personality disorders of the individual and into his emotional needs and their relation to mental health, this branch of medicine has in its applications tended to fall into one of two fields: clinical psychiatry and community psychiatry. This division is quite arbitrary, and the dividing line is by no means clearly drawn.

Community Psychiatry

In this discussion, our concern is with community psychiatry, which in turn, may be divided into two aspects: one, the positive or health-promoting aspect in which one would include family as well as general community attitudes and activities that afford opportunities and influences favorable to the achievement of

satisfactory social and personal adjustment to the individual; and, two, the diagnostic and therapeutic resources which the community provides for the psychiatric needs of its citizens.

Just as public health is a relatively late development of the general science of medicine so is the first or positive aspect of community psychiatry. If the aim of public health medicine is the extension of life and an improvement in its productivity, the aim of community psychiatry may be defined as the strengthening of personality and the improvement of its adjustment.

Both public health medicine and community psychiatry should be regarded as preventive medicine. From a somatic standpoint, preventive medicine seeks the most efficient physiological functioning possible for the organism. From a psychological standpoint, it seeks the richest possible functioning of the personality.

It is desirable that the body not be exposed to the stresses that interfere with the development of a normal growth pattern.

It is equally essential that the personality not be exposed to stresses that inhibit or distort its development in its process of maturation.

From its early objectives as an agency for the control of disastrous epidemics, public health medicine evolved to a broadly based philosophy of preventive medicine for the person in all of his biological, cultural, sociological, and environmental involvements. It was logical that with such a broad objective the prevention of one of the most frequent and devastating of illnesses—mental disorders—should become a matter of great concern.

Considerably earlier, however, another medical discipline had necessarily become concerned with the treatment of mental disease. For a long time, this branch of public medicine was limited to the operation of hospitals for mental diseases and still is in many States. In others, it has also come to include in its scope the education of the public in respect to the causes and prevention of mental and behavior disorders and to some extent the operation of clinics for their treatment. Perhaps there has developed some overlapping of objectives and functions rather than an integration through one governmental department assigned a comprehensive program of education and of hospitalization.

Somewhere Between

Why has mental hygiene, or the investigation and application of measures designed to establish and maintain mental health, become a function occupying a somewhat anomalous and divided place between two medical disciplines, each charged with public responsibility?

One discipline was originally concerned primarily with such activities as sanitation, control of communicable diseases, prevention of chronic diseases, occupational hazards, crowded living conditions, food handling, and other conditions that affect physical health.

It was gradually found that health problems were not all of mechanistic origin, that many of the problems found in the child health clinic, for example, did not have their origin in infections or malnutrition but in emotional difficulties or in interpersonal tensions. It was observed that most health problems had some related emotional component which for the establishment of most effective health must be dealt with by the techniques of mental hygiene.

It is often said that we have now reached the point in public health where further advance in the protection and improvement of the physical health of the population is beginning to require a mental health orientation. It is becoming well recognized that in its various services a health department meets a wide range of emotional problems.

The other medical discipline which rather naturally began to include mental health within its sphere of interest and activity was psychiatry. At first the establishment of asylums, largely custodial, was its principal contribution. Later as the mental hygiene movement began to gain ground, some of the superintendents began to acquaint the public with social problems created by poor mental health and to encourage the establishment of clinics for the diagnosis and treatment of milder personality and mental disorders.

Programs of mental hygiene in the States have been developed under one of two departments, either the health department or the division charged with administering the mental hospitals of the State. In some instances these two agencies are combined within a single department, along with other divisions of the

government concerned with the health and welfare of the population. Even in such a grouping, the two usually remain relatively separate in their functions.

Some Recommendations

Personally, I believe that in the larger States, at least, the department which controls the hospitalization of mentally diseased persons should be organized as a separate department with its chief executive officer responsible to the governor. Every State, of course, should have a mental health program, a part of which has a logical place in its general health department.

However, just as a psychiatrist is not qualified either technically or by his general orientation to the subject to be the administrative head of a department of health, so too the immediate direction of a department responsible for the operation of hospitals for the treatment of actively psychotic patients can scarcely be undertaken by one who does not have a wider acquaintance with psychiatry than that now acquired in schools of public health. Not every psychiatrist, either, is adapted to mental health work in a public setting. The majority are primarily trained to do individual psychotherapy.

I doubt whether the public health clinic is the setting in which the treatment of major psychiatric illnesses should be undertaken. Many patients who receive health department services do, however, have emotional problems even though they do not give rise to the categorized clinical reactions described in the textbooks.

The anxiety of the patient seen by the public health physician does not usually arise so much from the threat of weakening repressions as from some very realistic situation connected with the circumstance that brought him to the clinic. The anxiety felt by the breadwinner of the family who learned from a mass survey that he has pulmonary tuberculosis is not the anxiety felt by a compulsive neurotic.

Such anxieties are not treated by deep analysis but through the team therapy of the public health nurse, social worker, and the mental health-minded physician. In such a situation there is no place for the isolative tendency of the usual clinical psychiatrist.

But let us turn to the problem of mental health as it is associated with the activities of a State, city, or community health department, in which there should be a special division concerned with mental health. The time has come when public health should have a better understanding of cultural patterns of the community, of the inner feeling states which the public health worker will inevitably meet.

It seems to me that the schools of public health are not yet including sufficient psychiatry in their courses to prepare their graduates adequately for the directorship of a mental health division even though its emphasis will be on mental health rather than on mental disease, on prophylaxis rather than on therapy.

Public health personnel should be taught that many problems not previously considered as in the field of mental hygiene really belong in that sphere, that mental health and other services in a health department should be more closely integrated. There has been too great a tendency to separate psychiatric problems from their original context, a tendency which psychiatrists have unwittingly but frequently encouraged.

It is essential that the liaison between the mental health and the other divisions in the health department be quite close and that there not be the self-contained autonomy so often existing in bureaus. It would be highly desirable for the chief of a psychiatric division in a health department to have had some training in the social sciences, and to be aware of how people think and feel, of how they live within the social institutions and cultural patterns of the community.

Part of the General Health Program

What department should be responsible for the clinic which serves the ambulant mentally ill, the psychoneurotic and the psychosomatic patients? What department should direct such child guidance clinics as are not operated by privately endowed agencies?

All these clinics are primarily treatment in function and should be operated by the department that directs the administration of the mental hospitals, the department that I suggested be administered separately from the health department.

What, then, should be the function of the health department in respect to mental health? This should be preventive. There would be the greatest opportunity for reaching people who most need help and education in mental health matters if a mental hygiene service were integrated into the general health program of the local health officer. In practice, there is a great difference among the States as to the division of the mental functions and activities of a department of public health and those of a department of mental health.

Both types of departments have expanded their activities in recent years, yet there has been a tendency for health departments to be increasingly attentive to prophylactic and public education activities, while departments responsible for the administration of hospitals have increased clinical facilities for mentally ill or maladjusted persons.

Mental disease is one of the largest and most serious of health problems which may be approached by the usual methods of public health—emphasis on education, prevention, early case finding, and prompt treatment. These are the tenets that run all through the working principles of public health.

There is another and in many respects a wider view from which the subject of mental health should be approached. The need and demand for mental health services have become increasingly recognized, yet are so inadequately met and so poorly organized that there is need for comprehensive community programs to be established through local or State legislation.

One State's Findings

I will take the liberty to call attention to some of the conclusions reached by the New York State Mental Health Commission following its survey of the programs for mental health services throughout New York State.

The commission found that nowhere in the State were there adequate mental health services at the community level. Except for a few localities mental hygiene clinics were the only mental health service. At the local level there was no single governmental agency charged with the responsibility for community mental health. In some communities parts of the mental health

program were provided by health departments, education authorities, welfare officials, and by courts, but nowhere was there a central planning body for mental health services. As a result there was overlapping, duplication, and gaps in service, and overextension of their programs by some agencies.

The commission found that at the local level there tended to be fragmentation of services by reason of the fact that financial support, although limited, was available from a number of State departments and agencies.

The commission concluded that mental health services develop best in relation to needs when they are the responsibility of local government even though State financial aid and professional consultation might be necessary. As would be expected, it was found that mental health services have been developed by a variety of public agencies and by a large number of voluntary organizations.

The commission did not recommend the giving up of any existing qualified service. It was of the opinion that comprehensive programming for community mental health requires the combined efforts of health, welfare, education, judicial, and correction agencies, both public and private. It urged coordination and integration by a single, responsible agency of local government.

In reviewing community mental health services, the commission expressed the opinion that no community has a complete program if it does not have these five types of service:

The mental hygiene and child guidance clinics, inpatient psychiatric services in general hospitals, and the case-finding efforts of school systems, welfare agencies, and public health departments.

Rehabilitation services for the discharged or convalescent patient from the mental hospital.

The consultative services provided by trained mental health personnel to the professional staffs of other agencies, such as courts, schools, and welfare departments.

The educational activities carried out by mental health personnel, designed to inform other professions and the general public what has been learned from the clinical relationships

mental health personnel regarding the problems of human personality.

Specific efforts to deal with facts of community life in such a way as to reduce the frequency with which personality disorders occur. Other States will watch with much interest is attempt to secure complete and integrated mental health services.

Research in Program Methods and Evaluation New York State

By Herman E. Hilleboe, M.D., M.P.H.
Commissioner of Health
and George James, M.D., M.P.H.
Assistant Commissioner for
Program Development and Evaluation

The New York State Department of Health created a new unit in 1952 to assist the commissioner in evaluating the results of program activities and in promoting the development of new public health programs.

The new office is working toward the development of yardsticks for measurement of public health performance and is exploring methods for the determination of health need and accomplishment. It has stimulated local research throughout the State, in the belief that the future of public health activity in this area of changing priorities will be determined largely by patterns developed through local health activities.

The office of program development and evaluation consists of an assistant commissioner, a cultural anthropologist experienced in public health, a biostatistician, and, on occasion, an administrative officer. In addition to having full responsibility for statistical services, the director of the office also maintains technical supervision and general communication with all development, evaluation, and research activity throughout the department.

A few examples will illustrate the scope of this special team's accomplishments.

In Heart Disease and Hypertension

The new office has studied the entire problem of adult heart disease, looking for the best possible public health approach, and with a view to developing a program which would utilize tests for the mass detection and followup of both clinical and preclinical coronary heart disease and hypertension.

Projects of similar nature were visited; the literature was combed, and numerous consultants were asked for suggestions.

The Albany Cardiovascular Health Center project resulted. The center was devised to:

Detect and follow coronary heart disease and hypertension, determining the incidence, prevalence, and progress of these diseases among the participant group—2,000 male State employees in Albany between ages 40 and 54.

Determine the validity, reliability, and efficiency of the various techniques in the detection of these heart diseases during their preclinical or earliest clinical stage.

Develop and evaluate methods of applying these detection tests to large groups of the population.

Develop and maintain research teams which will perform satellite studies around the core testing program.

Offer an excellent periodic cardiovascular diagnostic service to 2,000 susceptible men, sending all pertinent data to each member's physician.

Stimulate and develop the interest of all State health workers in heart disease problems and programs.

Evidence has already been turned up that the history of cardiac symptoms elicited by the physician and the measurement of heart size by electrocardiogram and physical examination are both seriously lacking in reliability.

When the yardsticks for diagnosing and detecting heart disease are thus at fault, perhaps our major attention should be toward improving their scientific accuracy and consistency before further developing their practical application.

Six studies in the general field of heart dis-

ease have already been started, and many more are planned.

In Radiological Health

The protection of the public against dangerous radiation clearly concerns every health department. Radiation may come from naturally occurring radiation elements, X-ray machines, or materials that have been made radioactive by nuclear reactors. Because the use of radiation is increasing, a special problem faces the health officer.

The program development and evaluation unit is studying this problem. Special laboratory and survey equipment has been provided; a promising young sanitary engineer specially trained in radiological health has been appointed, and a technical advisory committee of radiation experts has been named. Existing knowledge on the need for a radiation control program was compiled, and a sanitary code regulation of great scope was recently passed.

An earlier regulation established standards for the 400 shoe-fitting fluoroscopes in upstate New York. This work in ionizing radiation control permitted the field engineers to gain technical knowledge which will be valuable in the more complete program now under way.

Special courses in radiation control are to be held for physicians. The sanitary engineers have already been given intensive training programs in both the field and the classroom.

In a Tuberculosis Program

A special team of well-trained public health people who are not personally identified with the tuberculosis program can often help us in taking a critical look at accomplishments and the yardsticks used to measure them. The new unit has surveyed the accomplishments in tuberculosis since New York's expanded control program began in 1947.

Among the interesting findings were:

The development of special yardsticks for the evaluation of case-finding services.

The clearcut delineation of areas with poor tuberculosis case-finding activities.

The decreasing yield of active tuberculosis found on the mass survey, by X-ray of adult

admissions to general hospitals, and among persons attending chest clinics.

The approximate cost per case of tuberculosis found by various procedures.

The proportion of those screened who are found to have various pathological conditions on followup.

The dramatic decrease in incidence and prevalence of tuberculosis at State mental hygiene institutions and the reasons why it is believed that this decrease is due to the department's efforts.

The great decrease in the number of patients reported as having "tuberculosis—stage undetermined."

The unchanging proportion of cases discovered from death certificates.

The importance of a new plan and studies governing the proper use of State and local tuberculosis hospitals and drug therapy for control of this disease.

In Cause-of-Death Reporting

The literature is filled with statistics based upon causes of death listed on death certificates. The new unit took a critical look at the accuracy and value of these statistics in New York State. By comparisons of autopsy and original death certificates on file, it discovered that while overall death rates might change little because of compensating factors of error, these compensating mechanisms cannot be expected to extend to the other factors associated with the death.

Hence, if these statistics are used as bases for epidemiological studies of what type of person dies from cancer, heart disease, or cerebral hemorrhage, for example, the use of cause-of-death data should first be refined. Also, multiple causes of death must be considered.

Perhaps our most promising point of attack against a chronic disease may lie in the correction of a condition which is not now listed on the death certificate. A simple example of this is the possible effect of obesity control on preventing death from hypertension.

The program and evaluation office has suggested that local health units use special pilot projects in searching out a new approach to the collection, tabulation, and use of cause-of-

th statistics for the assessment of chronic ease needs, programs, and accomplishments.

a Traffic Accident Study

Many agencies have studied the high annual l of accidents on the highways, but few have ie work along epidemiological lines. Insuf- ent data are available on the characteristics the population having a particular risk of hway accident. Some studies by the New rk State Public Works Department have nted out that drivers cannot be divided into se who drive fast or slowly. Rather it has n discovered that almost all drive over the ed limit 15 percent of the time.

The epidemiological problem, therefore, is re a matter of search for situations which ke any individual accident prone at a par- ular time. Such study requires careful at- tion to social science interview and survey hniques.

The evaluation team devised a special inter- ew questionnaire which was applied to area obability samples in two small cities. Many ctors were studied which might be associated th the occurrence or nonoccurrence of a motor icle accident.

In another project planned, observations will made of driver behavior, and interviews will conducted both on an area probability basis d also on specific individuals observed doing zardous or nonhazardous activities relating driving.

Fiscal Research

Recognizing that for most essential services e cost of public health programs and research ll continue to increase and that the money ailable for these services is reaching its limit, e State department of health, in cooperation th a temporary legislative commission, under- ok to study accounting and budget concepts at would be useful in controlling costs and at would provide administrators with a more ective tool for the measurement of alterna- e courses of action, the evaluation of per- mance, the development of priorities, and an nderstanding of the true costs of specific rograms.

A State tuberculosis hospital was selected for this. The specific principles or concepts tested were the accumulation of cost by program, func- tion, or area responsibility; the separation of costs into variable and fixed components; the relation of variable cost to workload for the use of standards for planning activities and ap- praising performance.

It is important to realize that costs alone can never be controlled, for it is the individual who makes the administrative decisions that result in costs. With complete information about the costs of all alternatives to a decision, the top administrator has sufficient fiscal data at his disposal to supervise the person making a de- cision with a cost implication.

Costs are also expressed in terms of work- load, thus permitting public health administra- tors and others concerned to have a more con- crete idea of what specific State appropriations are being used to accomplish an objective.

An important feature of this new system is its value to the health officer in the develop- ment of his long-range plans. If he knows the cost of each of several alternate plans, he will be able to adjust his program more readily to the funds allocated by the appropriating body.

Outpatient Management And the New Drugs For Tuberculosis Control

6

By Robert J. Anderson, M.D.
Assistant Chief
Division of Special Health Services
Public Health Service

New drug therapy for tuberculosis has raised many questions about tuberculosis control. You are all aware of the dramatic reduction in tuber- culosis mortality in tuberculosis hospitals through the use of streptomycin, para-amino- salicylic acid, and isoniazid. At this stage,

however, we should take care lest the spectacular performance of these drugs lead to undue reliance on outpatient therapy in dealing with a disease that still requires hospital management to a major degree.

It seems that isoniazid and para-aminosalicylic acid are for the present the first drug approach. Streptomycin may be held in reserve to cope with treatment failure and drug-resistant organisms.

Studies done by the Public Health Service and cooperating sanatoriums show that the maximum effect on making patient's sputum negative is obtained by not less than 16 weeks of therapy. Beyond 16 weeks of treatment, few of the remaining positive patients become negative, even under continued therapy. This is important in planning isolation of the patient. The momentum of X-ray improvement still continues after 32 weeks of treatment. Long continued drug therapy seems to be indicated, but exactly how long no one knows. Para-aminosalicylic acid is, if anything, a slightly better partner for isoniazid than is streptomycin.

The older the patient is, the longer he has had his disease, the less likely is a favorable treatment result. These observations emphasize the importance of early case finding to achieve maximum effective treatment and to reduce the proportion of patients who arrive at a chronic stalemate in their struggle with their disease.

On the hypothesis that isoniazid may possess prophylactic qualities, the Public Health Service now is undertaking an extensive study to determine the possible value of the drug in preventing complications of primary tuberculosis in children, particularly tuberculous meningitis.

Importance of Case Finding

Plans are now going forward to coordinate the study in pediatric centers throughout the United States and Puerto Rico. Patients selected for this investigation will be treated under a uniform protocol. The results will be assessed centrally by the physicians working in these centers. Possibly the future will see the extension of drug prophylaxis to the prevention

of tuberculous infection in a tuberculous environment.

It has been observed that when the patient's sputum persists bacteriologically positive, in spite of drug treatment, some of the bacilli remaining demonstrate a resistance to that drug. Isoniazid-resistant tubercle bacilli are virulent for some animals and avirulent for others. We do not yet know that the patient who is sputum-positive with some drug-resistant organisms after drug therapy does not spread disease to other humans. This is a challenging subject for an epidemiological investigation of significance to the future practice of tuberculosis control.

Case-finding activities continue in importance in the control of the disease. Not so long ago case finding was held back because no treatment was available for the cases discovered. Now, is it not logical, as treatment becomes more effective, more available, and less costly, that we devote more of our resources to this and the other activities in control?

Changes in Hospital Practice

The effectiveness of the drugs has changed hospital practice, both in therapeutics and in medical administration. Within the hospital there are shifts occurring in the use of such techniques as pneumotherapy, thoracoplasty, and pulmonary resection.

The duration of patient stay is being effected, for patients either obtain maximum hospital benefit earlier or are saved from what previously were progressive and fatal disease processes.

Studies of hospital phenomena are needed to show the exact changes occurring in the way hospitals are playing their role. Earlier discharges are vacating tuberculosis hospital beds. These may remain unfilled to the extent that the rate of discharges exceeds the development of new cases, that outpatient diagnosis and treatment are substituted for hospitalization, and that patients with other medical or surgical problems of the lungs and chest, or with other chronic diseases, are permitted or refused admission.

For practical purposes newly reported cases

are a useful measurement of the incidence of tuberculosis disease. In 1953 the States and Territories reported 113,531 cases of tuberculosis, a decline of only 3.5 percent from 1952. This 3.5 percent reduction in new cases does not keep many tuberculosis beds vacant.

Outpatient Management

Streptomycin, para-aminosalicylic acid, and isoniazid are effective, cheap, and easily administered, leading to an extension of therapy beyond the hospital.

There are several circumstances under which outpatient drug treatment is employed. One, the common practice of continuing treatment after early hospital discharge, seems consistent with the knowledge we possess of the effects of the drugs on sputum status and clinical improvement.

Another circumstance which leads to outpatient treatment was a marked insufficiency of tuberculosis hospital beds for the patients. In the pre-drug era we put patients in waiting lists until we could hospitalize them. Now we put them on drugs.

Long continuous therapy is more uncertain out of the hospital: Patients do not like the routine of taking pills daily, do not tolerate nausea, dislike being jabbed with needles for twice-weekly streptomycin injections. Nevertheless, some improve.

Should I ask you, then, to believe that outpatient therapy, without rest (some patients continue to work), without proper diet, without surgery when necessary, will produce an equal result to hospital management?

Also, an increase in outpatient treatment results when physicians retain their patients instead of referring them to available beds in hospitals and health departments as in the past. For its effect on public health practice, outpatient treatment under this circumstance must be evaluated not alone in terms of patient survival, patient recovery, patient relapse as compared with hospital care data, but also in terms of case reporting, continued case supervision, patient education, contact examination and supervision, sputum conversion rates, and infection rates.

Although we need to define the role of outpatient treatment, for the time being, for the welfare of tuberculosis patients and their families, it is incumbent on us to emphasize the advantages of hospitalization for prompt recovery and the protection of the family.

When a tuberculosis patient is to be an outpatient, the health department should see that he has:

A home environment that will be conducive to optimum therapy, including satisfactory provision for protection of family and neighbors.

Adequate nutrition as demanded by a therapeutic regimen.

Necessary assistance for the family, with direct reference to their financial, social, and psychological needs.

Adequate bedside nursing.

Proper diagnostic treatment and followup services, including radiological and laboratory examinations.

Health education for both patient and family, as a means of maintaining the high level of community protection which institutional care normally affords.

Finally, the drugs themselves, in adequate supply to maintain optimum therapeutic levels.

Preliminary Observations

The Public Health Service has recently undertaken a study of the characteristics of non-hospitalized tuberculosis patients, the kinds of services they are receiving, and how they appear to be faring.

Here are some preliminary, rough observations:

Approximately half of the known active tuberculosis cases are hospitalized, and one-half are at home. Of those at home, two-fifths have drug therapy recommended, and the remainder are at home with no recommendations known to the health department for drug therapy.

Health departments find it difficult to determine which of the known cases at home are active. Preliminary tabulations show that on the average 20 to 35 percent of the known active cases at home have not had a clinical examination or X-ray within the preceding 12 months. A similar proportion have not had a determination of their bacteriological status. Even

though rest and restriction of activity is still considered an essential part of the treatment for tuberculosis, approximately half of the cases at home were not given any specific recommendations in this regard.

These preliminary tabulations indicate that there are very marked variations in the adequacy of care that patients are receiving at home, and that many of them are getting no more home care than in the pre-drug era.

You might say that although the drugs are spectacular there is still no evidence that they can do for tuberculosis what penicillin has done for syphilis. Many cases still need this combination of preliminary hospitalization, surgery, and laboratory control. The drugs should not make us less active in finding cases, keeping patients and their contacts under public health supervision, and educating the public about tuberculosis.

Infectious Hepatitis, 1953 and 1954

Infectious hepatitis was added in 1952 to the list of diseases to be reported weekly, but notification was known to be incomplete for that year. During the following 2 years reporting was much improved and was probably better in 1954 than in 1953.

A high incidence of the disease occurred during the late winter and early spring months of 1954. For the corresponding period in 1953, the chart shows a bimodal distribution which probably reflects reporting procedures rather than an actual seasonal trend. Although incompletely reported, the 1952 figures indicate a definite peak in February, as in 1954.

The incidence decreases during the summer months and may reach a low point sometime during the fall months. Sufficient data are not available at this time to establish the season of lowest incidence.

The provisional number of cases reported in 1954 is 49,739 compared with 33,382 for 1953. The large number of cases reported during these 2 years indicate that the disease is a major health problem. This is particularly true in certain areas of the United States. More than a third of the cases for both years were reported from the Middle Atlantic and South Atlantic States. A large number of cases were also reported in the West North Central States, especially during 1951.

This material was prepared by Granville Sylvester and Dr. C. C. Dauer of the National Office of Vital Statistics, Public Health Service.

Number of cases

Infectious hepatitis in the United States, by week: 1953 and 1954.

During 1953 and 1954 approximately 60 reports of epidemiological investigations of outbreaks of infectious hepatitis were received by the Public Health Service. These reports accounted for less than 3,000 of the total cases reported.

Many cases were not considered associated with outbreaks, and reports of outbreaks were not received from many States. Some States probably did not report outbreaks because the cases usually occur over a period of several months as the incubation period of the disease is from 15 to 35 days.

The mode of spread for most of the outbreaks was given as personal contact. Food, milk, and water have been considered a vehicle of infection, but in only four instances during 1953 and

1954 was water considered as a possible vehicle. Food and milk were not suspected as vehicles in any of the reported outbreaks, which occurred most often among institutional or school populations. In several instances the disease was associated with unsanitary living conditions and was among persons in the low socioeconomic group.

An unusual characteristic of the disease is the long period, 6 weeks to 2 months, of convalescence from the infection. No successful treatment has been found, and in some cases the infection leaves chronic liver damage. Gamma globulin has been used successfully for prophylaxis. It gives passive immunization and is effective if given to contacts during the early part of the incubation period.

To summarize in systematic order the reports of progress in arteriosclerosis research supported by grants of the Public Health Service, Dr. Murray Goldstein prepared for the National Advisory Heart Council and for limited distribution a detailed and documented account of the studies and their relation to the pathogenesis, treatment, and prevention of this disease. Dr. Goldstein is an assistant to the chief, Grants and Training Branch, National Heart Institute, Public Health Service.

The following paper, drawn from the original report, aims to call attention to the general scope of

the research, rather than to evaluate individual findings or to describe them in precise detail. At this stage, with so much still unknown and with many studies still in progress, it is not possible to establish an accurate perspective. Also, this paper excludes much valuable work that is unpublished or is supported by institutions other than the Public Health Service. Compressing the information and arranging it in this context has inevitably resulted in somewhat arbitrary statements and has perhaps strained the intended meaning of the reports by the scientists.

Arteriosclerosis Studies

RESEARCH in cardiovascular health is a prime function of the National Heart Institute, a division of the Public Health Service. Since its founding in 1948, in addition to conducting research in Government laboratories, the institute has granted more than \$3.5 million to universities and other institutions to support research related to studies of arteriosclerosis. Most of this amount applies to studies which are still in progress.

The pattern of this research is determined largely by the applicants for grants. The scientists themselves pose the questions which must be answered in advance of further progress in the field.

Definition and Classification

Relatively few grants have been sought for defining the entity of arteriosclerosis, that condition marked by loss of elasticity, thickening or hardening of the arteries, or atherosclerosis, a specific type of arteriosclerosis characterized by lipoidal and plaque-like changes in the innermost layer of the artery, the intima. One definitive project classifies an entity known as coronary

heart disease, from studies of heart muscle lesions. Correlated clinical findings and electrocardiograms are offered to support this diagnosis.

Experimental Studies in Pathogenesis

The need to develop experimental techniques is both primary and chronic in the search for contributing factors in arteriosclerosis. The successful use of animals to induce sclerotic processes comparable to those in man began with Anitschkow's work with rabbits in 1908. Since then, experimental studies have employed guinea pigs, rats, dogs, cockerels, chickens, rabbits, and Cebus monkeys. Work supported by the Public Health Service has produced many basic contributions to experimental techniques, involving control of diet, administration of chemicals, action of hormones, transfusion of serums, physical injury, genetic influences, and the effects accompanying aging.

An early need in experimental techniques was to develop simple and reliable methods of inducing the process of arteriosclerosis. Cholesterol, a lipid found in animal fats and oils,

whole milk, egg yolk, liver, and certain forms of seafood, was associated with the sclerotic process by Anitschkow. Since diets high in cholesterol do not invariably produce the condition, other contributing forces have been looked for. Low thyroid activity is one. Arteriosclerosis develops in dogs fed a high cholesterol diet supplemented by thiouracil, a chemical which reduces the production of thyroid hormones. The thiouracil does not so affect dogs on a normal diet.

Readings of cholesterol in the serum of dogs are used in efforts to predict the severity of arteriosclerosis. The injury regresses if the serum cholesterol falls below a certain level. Once the necessary fatty state in serum is established, arteriosclerosis may develop in a matter of days or even hours.

Instead of using thiouracil or thyroidectomy to induce arteriosclerosis in dogs, a laboratory may save time and effort by using radioactive iodine to depress thyroid activity. Curiously enough, the loss of thyroid activity resulting from surgery, followed by an associated rise of cholesterol in the blood, does not produce coronary atherosclerosis in patients with a history of cor pulmonale, a heart disease secondary to disease of the lungs, or rheumatic heart disease.

A process for inducing atherosclerosis for experimental study, without prolonged cholesterol feeding, consists of planting diethylstilbestrol, a synthetic chemical with action resembling a female sex hormone, under the skin of a chicken. This chemical produces a sustained condition of excess lipid in the serum of chickens and, consequently, arterial lesions which closely resemble those found under controlled conditions.

Rats resist efforts to induce arteriosclerosis even when diabetic, although it is common to find atherosclerosis associated with diabetes in humans. On spectral analysis, the fatty proteins in rat serum differ from those of other experimental animals. Rats, which fail to develop a high level of cholesterol in the blood on a fatty diet, rapidly develop such a condition on the identical diet when rabbit serum is transfused into them. This experience suggests that the difference between rat and rabbit plasma may be the basis for the difference in susceptibility of these species to arteriosclerosis.

A study of the relation between physical in-

jury to the artery wall and the formation of atheromatous plaques finds that weanling albino rats are remarkably resistant to the consequences of injury induced by injection of sodium acetylsulfathiazole. The severity of the consequent lesions increases with the age of the rats injured. Injury to the artery wall of rabbits subsequently fed a high cholesterol diet produces a lesion similar to human arteriosclerosis. Of associated interest, microscopic studies reveal hemorrhage within the artery wall in sudden human deaths from coronary artery disease and coronary atheromatosis.

Fundamental Studies

The driving forces in the arteriosclerotic process may be in the fluids surrounding the artery wall, in the behavior of the cells of the wall itself, in various forces of environment or custom, in genetic influence, or in a combination of several conditions.

The Artery Wall

Studies of the cellular metabolism of the artery wall itself have been stimulated by the realization that atherosclerosis may occur without the appearance of excess fat in the plasma. One such study demonstrates that the rat artery may convert acetate into fatty acids and can incorporate phosphorus into the phospholipid molecule. The artery wall itself thus can contribute to the production of lipids. To facilitate similar studies, an investigator has developed a technique for measuring the metabolism of intact arterial tissue under aseptic conditions.

Some spontaneous coronary artery lesions of birds are found to be fibrotic rather than fatty; fats may have a late part even in the forming of arteriosclerotic plaques in the aorta of old dogs. Another investigation finds that mucopolysaccharide deposits occur before the lipids. These studies are associated with other efforts to work out the precise cellular history of what appears to be a proliferative and degenerative disease.

The aging factor in the arteries has been associated with the formation of bone or cartilage in the aorta of senile rabbits. Calcification of the media, another sign of aging, is said to precede the formation of intimal plaques, although this

conclusion is not supported by other studies. Autopsies demonstrate that arteriosclerosis increases with age in both sexes. It is more severe, however, in the male. The relatively greater susceptibility in boys appears before their 10th year.

Still other techniques are being developed to pursue the study of the role of the arteries in the hardening process.

The Artery's Surroundings

Studies of the artery's chemical and physical environment deal with three main fields: cholesterol and phospholipids; lipoproteins; and physical forces, including blood stream pressure and turbulence.

The presence of cholesterol and its esters in diets, in plasma, and in arterial plaques associated with arteriosclerosis has commanded particular attention.

The work of identifying, measuring, and exploring the metabolic processing of these lipids deals with the production and destruction of cholesterol, the differentiation between cholesterol taken in the diet and that formed by the body, and the activity of "trace companions" of cholesterol as atherosclerotic agents.

The fate of cholesterol in the intestine is affected by certain micro-organisms and by chemical conditions which may prevent or accelerate its absorption into the blood stream.

The liver is the chief organ for removing excess cholesterol from the blood. It excretes 60 percent of the excess as bile acid. When unknown forces prevent the return of plasma cholesterol to the liver cells, an excess of fat appears in the blood.

Young animals appear to form more cholesterol in the liver than their elders. Low calorie diets reduce the rate of such formation; high calorie diets restore it. The rate is depressed by a high fat diet, which also seems more effective than a low fat diet in removing cholesterol accumulated in the liver of rats. A high level of cholesterol in the blood does not appear in dogs with deficiency of magnesium or in the liver of rats with a deficiency of pantothenic acid. A deficiency of pyridoxine is accompanied by a high level of cholesterol in the blood of Cebus monkeys and rats, but not in rabbits. Even with a calorie deficiency, chicks on a high

cholesterol diet have excess cholesterol in the blood and develop atherosclerosis. As calorie intake rises, successive increments of blood cholesterol decrease. Other dietary fats in combination with cholesterol appear to induce higher fat and cholesterol levels in human blood than cholesterol alone.

Detergents, which have a wetting action that keeps fats and oils in suspension so that they do not cling to affected surfaces, increase all blood lipid components, especially phospholipids. An increase in phospholipids appears to retard or prevent atherosclerosis. The ratio of blood cholesterol to blood phospholipid (C/P ratio) may be of importance in retarding atherosclerosis.

Two substances found in the blood stream, known as lipanogen and antilipanogen, respectively, support or oppose the forming of visible fat granules in tissue culture. As cholesterol combines with antilipanogen, the opportunity for lipanogen to create fat is enhanced.

Obstruction of the bile duct has been associated with high cholesterol levels in the blood. On the assumption that these levels are supported by the action of retained bile salts, it was discovered that cholate impedes the transfer of cholesterol from plasma to liver. High blood cholesterol may be a development secondary to disorder of cholate metabolism.

In addition to occupation, housing, and dietary patterns, genetic factors may be significant in the tendency to form cholesterol.

Cholesterol and phospholipids in blood exist in combination with proteins rather than in a free state. Such combinations are known as lipoproteins. The amount of lipids in such proteins is measurable by a flotation process which permits analysis according to the density of various classes of lipoproteins in plasma. These are classified in terms of Svedberg flotation (Sf) units. Four laboratories engaged in such investigations are participating in a cooperative study on lipoproteins and atherosclerosis.

Efforts to measure the volume and forms of lipoproteins in the blood and in fixed tissues are proceeding with the prospect that these measurements may help to predict the imminence of atherosclerotic change, to diagnose the present degree of atherosclerosis, and to guide the management of the condition and its consequences.

If it is determined what classes of lipoproteins are most formidable, preventive or therapeutic measures may follow.

Because the level of serum cholesterol and lipoprotein has been found to vary in men over a 10-week period or more, single readings may not serve as a reliable indication of a patient's condition.

The liver, one of the organs which produce lipoproteins, increases its output of certain classes if it is chronically inflamed or if it is poisoned by carbon tetrachloride. Hepatectomy causes a gradual decline in all lipoproteins.

Animal species vary in their typical patterns of lipoproteins and in their susceptibility to the effects of different lipoprotein classes. Young women have more alpha lipoprotein fractions (associated with alpha globulin) and fewer beta fractions than young men. Many men and older women tend to have lower levels of albumin and alpha lipoproteins and relatively higher levels of beta lipoproteins than young women. (This information correlates with the greater tendency of men and older women to develop atherosclerosis.) The same tendency appears in patients with clinical signs of atherosclerosis, as well as among persons with diabetes, nephritis, and xanthomatosis, even when their cholesterol or C/P ratio is not elevated. The level of Sf 12-20 beta lipoproteins is higher in persons with diabetes if they are also arteriosclerotic. The concentration of such lipoproteins has been reported to be a more accurate indicator of atherosclerosis than the cholesterol level. In some circumstances, it is this lipoprotein factor which links obesity with atherosclerosis.

Effects of heparin, a normal trace constituent of the blood, are undergoing extensive study in the search for a chemical which may influence the formation of arteriosclerosis.

Physical forces examined in relation to arteriosclerosis include surface tension (detergent action), filtration of fats by artery and capillary walls, turbulence of blood in the aorta of rabbits, and elevated blood pressure (hypertension). Although hypertensive patients show a high incidence of arteriosclerosis, the experimental evidence so far does not establish that the one condition necessarily induces the other.

Clinical Studies

There have been no research projects on the incidence of morbidity from arteriosclerosis because of the difficulties of reliable diagnosis.

A reliable method by which the incidence or severity of arteriosclerosis could be measured objectively has been the goal of many investigations. Determinations of serum cholesterol, cholesterol tolerance, lipoprotein fractions, phospholipids, cholesterol-phospholipid ratio, lipofanogen-antilipofanogen ratio, or neutral fat have been suggested as possible indexes of the probability of developing or having already developed arteriosclerosis.

In man, excluding histological study after biopsy or necropsy, the only reliable method of diagnosis at the present time depends on the onset of symptoms associated with a decreased blood supply to specific organs or parts of the body. For better objective evaluation of these observations, many methods and devices have been suggested and are being perfected; some of these are flicker flame photometry, plethysmography, ergometry, electrocardiography, vector cardiography, ballistocardiography, vascular catheterization, roentgenography, and angiography. As yet, no generally acceptable means has been agreed upon for the preclinical diagnosis of arteriosclerosis.

Prophylaxis and Therapy

Diet, medication, surgery, and rehabilitation are being studied as means of preventing or treating arteriosclerosis.

The administration of adrenal cortical and corticotrophic hormones is associated with high levels of cholesterol and lipids in the serum without an increase in lipoproteins or in atherosclerosis.

The relative susceptibility of males to arteriosclerosis has encouraged studies of the effects of synthetic and natural sex hormones on the occurrence and treatment of this disease.

Studies of thyroid effects find that administration of thiouracil or thyroidectomy does not cause regression of arteriosclerotic lesions in dogs.

After biological experiments indicated that

a portion of the mammalian brain affects the movement of cholesterol into the blood stream, a lipid-poor, cholesterol-free residue of this organ was fed to patients with arteriosclerotic heart disease and a high level of cholesterol in the blood. Their serum cholesterol fell "significantly," presumably as a result of the chemical effect blocking the absorption of sterols in the intestine.

Common "lipotropic agents" necessary for fat metabolism, such as choline, methionine, and inositol, have no beneficial effects on the incidence or severity of arteriosclerosis. Ferric chloride decreases absorption of cholesterol from the alimentary canal but not its production by the liver. Other chemicals which reduce absorption are sitosterol and dihydrocholesterol.

The prospect of prophylaxis by diet is not materially brightened by studies to date. A decline in Sf 12-100 lipoproteins accompanies a loss of weight. The Kempner rice diet reduces serum cholesterol and the C/P ratio. It is not certain that restriction of cholesterol in the diet will ordinarily reach the level needed to produce clinical results. The amount of cholesterol in the diet may vary widely without

producing marked effects on the levels in the blood. Restriction of cholesterol in the diet must be accompanied by considerations of total nutritional needs, such as the part proteins play in lipid metabolism.

Surgery to repair or replace vessels damaged by arteriosclerosis has employed a variety of techniques. These include generation of inter-coronary vessels in a heart inflamed by abrasive asbestos powder; grafting of substitute arteries which have been dehydrated or taken out of cold storage; the use of prosthetics made of metal, plastic, latex, or thorotrast; and the patching of arterial walls with peritoneum. The technique of grafting has evoked studies of optimal length, source, structure, sterilization, and storage of blood vessels.

Studies of rehabilitation of cardiac patients are actively encouraged. Energy requirements, as measured by oxygen consumption, are being measured for various occupational activities.

Most of the clinical studies noted here are undertaken in association with experimental laboratory studies, in order to assure that the patient will have the advantage of validated theories, technical experience, and full understanding of the biochemical factors.

PHS films

Arthropods of Public Health Importance

35 mm. filmstrip, sound, color, 7 minutes, 42 frames. 1954.

Audience: Entomologists, parasitologists, sanitarians, and students interested in arthropods.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

Arthropods of public health significance are featured in this filmstrip.

Rhodnius prolixus, a kissing bug

It shows the outstanding characteristics of some of the more common insects and in a few instances gives the life cycle of one or more species of a particular arthropod. Included

are: cockroaches, mosquitoes, flies, bedbugs, *Triatoma*, fleas, lice, scorpions, tarantulas, spiders, centipedes, ticks, and mites.

Centruroides, a poisonous scorpion from Arizona.

Legal Note *on public health*

Court Acceptance of Delayed Birth Certificate Filed by Court Order

The recording of a birth certificate was held by the Federal District Court, in the case of *United States v. Casares-Moreno*, 122 F. Supp. 375 (S. D. Cal. 1954), to be only prima facie evidence of its validity, even though it was filed pursuant to an order of the Superior Court of Los Angeles County, and was subject to rebuttal.

The defendant, on trial as an alien who attempted to enter the United States after his deportation, produced a public birth certificate, filed with the California registrar under delayed filing procedures, showing that his parents had given birth to a son in the United States. The birth certificate indicated on its face that it was offered for filing pursuant to order on August 13, 1936, of the Superior Court of Los Angeles County.

The prosecutor, in rebuttal, contended that the son born in the United States was not the defendant but his brother and that the defendant had taken the name and identity of the brother.

The jury found that the defendant was not born in this country.

The defendant did not contest the court's proposition that ordinarily an instrument which the law required to be recorded is only prima facie evidence of the validity of the instrument. He did contend that since the birth certificate in question was recorded pursuant to an order of the superior court it thereby gained some higher status and became a judgment which under the full faith and credit clause of the Constitution had to be treated as a conclusive adjudication of facts stated therein.

The Federal District Court rejected this contention on the following grounds:

"There is no indication that the California Legislature intended to raise records or parts of records so belatedly established to any greater status than the normal registration records which are never, in cases of birth recordation, to be taken as irrebuttable evidence. In other words, it appears that the role of the superior court in ordering the recordation partakes of an administrative function. It is merely an act of recordation which has been permitted by judicial action rather than by an administrative officer. The judgment in such action is not that the facts so found are absolutely conclusive as between petitioner and the rest of the world, but rather, the judgment is that the registrar is ordered to make such a recording."

The court went on to say:

"It is important to note that even if the California Legislature did intend that such a determination was conclusive (which this court finds it did not intend to do) such an intention would, most probably, run afoul of Constitutional prohibitions. Making such an ex parte appearance conclusively establish the facts surrounding a person's birth or death might well infringe on and conclusively determine the rights of any third person having contractual or other relations with, and regulatory duties concerning, such person. This would appear to deny such third person due process."

For a similar holding see *Ex parte Lee Fong Fook*, 74 F. Supp. 68 (N. D. Cal. 1948), where the Federal District Court held that jurisdiction to adjudicate citizenship status of a United States resident has never been conferred by Congress on State courts and, consequently, any State court judgment purporting to exercise that jurisdiction cannot, to that extent, claim of the Federal courts full faith and credit.

Department of Health, Education, and Welfare.*

Evaluating Program Progress

By ANDIE L. KNUTSON, Ph.D.

EVALUATION is concerned with determining value or worth. Each of us is constantly making evaluations in our everyday lives. We judge ideas or actions in terms of right or wrong, good or bad, honest or dishonest, and practical or impractical so frequently and so quickly that we are often unaware that we are doing so.

We draw upon the full range of our experiences in making these judgments or evaluations, testing each one against our personal and professional patterns of value or concern and against estimates of their relevance to the situation at hand. This weighing process may be either conscious or subconscious, objective or intuitive. Thus, decisions are often made without adequate consideration of pertinent facts available; sometimes they are made without considering the possibility of obtaining such facts.

Program evaluation is concerned with determining the worth or value of efforts to achieve a given purpose or objective. The specific purposes of evaluation in this situation are to provide objective estimates of achievement and to provide guidance for the conduct of program activities. To achieve these purposes, two types of evaluation are required—first, “evaluation

of program achievement” and second, “evaluation of program progress.”

Sound evaluation studies of program achievement are essential if we are ever to know whether or not we are attaining the goals for which we strive. The public, too, has a right to know whether our efforts and money are well spent.

Concrete and valid evidence of the achievement of public health programs is frequently most difficult to obtain. Many of the objectives are broad and hard to reach. Often we may not reasonably expect observable positive results until the program has been under way for years. With some hold-the-line operations, failures are easier to define than successes. Many outside influences quite apart from public health efforts may effect the achievement of the long-range objectives in positive or negative ways. On-going program activities must be continued in the best possible manner even in the absence of the measures of achievement which are only available after the program has been in operation for some time.

Program Progress

Thus, the process of evaluating program achievement is not adequate for satisfying the second of the two objectives of evaluation—providing guidance for program activity. To achieve the purpose of program guidance, objective data need to be obtained and applied throughout the phases of program planning, development, and operation. Objective evaluation must take its deserved role as part of the daily routine of each health worker.

Dr. Knutson, chief of Behavioral Studies, Division of General Health Services, Public Health Service, presented this paper in part at Pennsylvania's Third Annual Health Conference held at State College, August 1954.

In the course of evaluating program progress, it is possible to identify difficulties or barriers as they occur and to make necessary changes on the basis of the best objective data available. Sound evaluation of progress made as a program continues day by day can help to assure that each new phase of the program is built on the positive achievements of the preceding phases.

The concept of evaluating program progress is of value whether we think in terms of the health department program as a whole, in terms of a particular program, or in terms of the efforts of the individual health worker with his personal and team responsibilities.

The purpose of evaluating program progress is to improve the quality of decisions made at any point during the planning, development, and operation of a program.

Since many programs are in operation concurrently in any health department, different types of decisions may have to be made at the same time. Overlappings occur, but for the purpose of this discussion, I have grouped the program decisions to be made into the four broad types of those concerned with:

1. The nature of the interests, wants, or needs the program is intended to satisfy.
2. The broad purposes of the program and the philosophy of approach or policies to be followed in trying to achieve these purposes.
3. The selection or development of the methods, techniques, or procedures to be used in the program.
4. The application of philosophy, policies, and methods in carrying out the operation of the program.

Interests and Needs

We all tend to assume that other people want and need the same things that we would want and need if we were in their situations. We assume we know what they need, without recognizing that in making that assumption we are making a decision. An important question of progress evaluation is: Have the interests, needs, or wants we are trying to satisfy been adequately identified?

Exploratory fact finding is one way of assuring adequate identification of needs or wants.

Questionnaires, interviews, projective tests, group discussions, analysis of statistical data—all sorts of techniques can be used to gather necessary data. Whichever method is used, it is important to try to obtain the other person's identification of needs or desires from his point of view—as he describes them. We need to be careful that the very nature of our questions or approach does not limit his thinking to our own ideas about the possibilities.

The methods of obtaining data for use in evaluating program progress do not need to be complicated. In fact, often the simplest method yields the greatest return.

The nurse who encourages a mother to pour out her troubles and waits patiently for her to identify the things with which she needs help is applying one of the best exploratory techniques. Sometimes simply helping the mother to formulate the problem clearly will enable the mother herself to identify some constructive action to take. Maximum value of the technique occurs when the nurse makes sure that she has given some help on as many as possible of the specific things identified. Referring the mother to some other source of assistance is sometimes as effective as providing her with materials or guidance. Knowing how the mother perceives her problem may be the key to developing an effective solution. If the solution is meaningful to her, there is a much greater likelihood that she will carry out the action after the nurse leaves.

No public health worker has the time and opportunity to make a thorough study of the other person's interests, wants, and needs every time a decision has to be made. But all of us can profit by identifying as a decision each assumption we make about needs and by being as objective as we can in making that decision. We can all profit also by trying out the more thorough method of exploration with a part of the case load. For example, it might be possible to apply this principle regularly on the first home visit or restaurant inspection carried out each morning. Although initially more time will be spent in these instances, the additional effort may help to identify and solve problems that might otherwise drag on indefinitely.

The same principle applies in identifying community needs. Recently a health educator

in a local community seeking to identify the needs upon which to build a sound health education program first made a survey of public health needs. She identified little that was new or unexpected and was unhappy with the findings because she was certain many health problems were not being reported.

She reviewed her approach and found that she had used questions about health needs and public health problems that meant more to the public health worker than to the people she was interviewing. She had encouraged responses in terms of existing services only and her own ideas about new possibilities. On the basis of this evaluative review, she changed her approach and tried a more open interview which encouraged the respondents to discuss freely the little things families run into when they first move into the neighborhood.

Using this new method, she found that many were concerned about uncontrolled dogs roaming the neighborhood. Others mentioned the need for some type of recreation facilities for preschool children who were playing in the streets since there were no sidewalks. Expectant mothers did not know where to reach the nearest physicians. Mothers with young children desired help on behavior problems. Thus, the open question approach, which was focused toward identifying the problems from the mothers' point of view, yielded data of great value in defining the goals for a community action program.

Purposes and Philosophy

The second major type of program decisions to which progress evaluation can contribute are those concerned with the development of the purposes and philosophy of the program. The second question can be stated as follows: Have the program objectives and philosophy and policies been fully agreed upon, formulated, and written down?

Misunderstanding about the broad purpose of a program and the philosophy of approach or policies to be followed in trying to achieve this purpose is a common source of friction. Often sources of potential conflict can be identified in the beginning of the program through frank and open discussion by all persons directly con-

cerned. Writing down agreements helps to assure clear and workable formulations.

In one instance, discussion along these lines after a program had been in operation for 5 years revealed serious misunderstandings among the members of the staff. Some had perceived the project as a community demonstration program to be discontinued as soon as the local health department was prepared to take over. Others saw it as a research project to test methods of diagnosis and control. They were unaware of the problem of preparing the community for its role. A few perceived it as a program to provide services and seemed unaware of any other purposes. Those who clearly identified the purpose as a demonstration were in disagreement about what they were trying to demonstrate and to whom.

Stating the goals of a program in terms of specific health practices is a good way of keeping plans concrete and practical. This is more than an exercise; it is a test of sound planning. Unfortunately, some of our health objectives are long range and hard to pin down. When they can be specifically identified in this way, however, methods of achieving them can be selected with greater confidence.

If the goal is to influence a specific health practice, such as food handling, it is possible to find out how this particular practice is related to the habit patterns and interests of the people concerned. We need to know how the program ties in with their ways of thinking and behaving, with their way of life. For it is unreasonable to expect ready acceptance of health practices that conflict with personal interests or deep-seated habit patterns.

Clear formulation of objectives requires identifying the intermediate goals that need to be achieved in order to attain the program objectives. Almost any program can be broken down into intermediate steps that can be measured. If the measurement shows that the step has been achieved, one can feel confident in going forward to the next step. If the data suggest that this intermediate step has not been attained, it will be important to find out the reason for failure and pause long enough to find a more effective method for achieving the intermediate goal.

In evaluating progress, it is important to dis-

quick and easy approach. Exhibit evaluators ask each exhibitor to complete in about 25 words this sentence: "The main purpose of this exhibit is . . ." Then they ask a number of members to complete the same sentence while observing the exhibit. In one instance all the observers wrote, "The main purpose of this exhibit is to demonstrate the various uses of isotopes." The exhibitor wrote, "The main purpose of this exhibit is to demonstrate various techniques for testing laundry equipment."

A somewhat similar approach can be used to test whether the practice recommended makes sense to the other person and whether he can easily apply it in the manner intended. A Public Health Service psychologist is studying patient reactions to a low sodium diet booklet. As part of the test, he and his wife went on the recommended diet for several days. They came out with new respect for the difficulties faced by the patient. They had considerable trouble, for example, in using the index, which had been set up from the point of view of a nutritionist, to find such common food items as peanut butter and salad dressing.

A Public Health Service nurse in developing materials for the use of diabetics tried to carry out the exact process outlined in the instructions for injecting insulin. She found it physically impossible to perform all the tasks alone as recommended.

Many health departments are now routinely using tests to tell whether their written materials will be understood by the groups for which they are prepared. The Dale-Chall and the Flesch tests of readability are easy to use. The Flesch test requires only a count of the number of syllables per 100 words and the average number of words per sentence. With these two facts it is possible to estimate the grade level of reading ability required. After some training, any clerical person can apply the test successfully.

For example, one health department, while carrying out a mass X-ray campaign for tuberculosis, received 3 or 4 calls a day from people who asked for an explanation of the notices they

had received about the X-ray findings. An analysis of the reading ease of the notice showed that about eighth grade reading ability was required to understand the message; thus the message could be understood by only about half of the adult population of the community. Since it was important that everyone understand this message, it was simplified to about the fourth grade level of reading ability; then it was tried out on a number of people with low education to make sure that they interpreted it correctly. The health officer has since reported that no calls for explanation are now received.

Major emphasis has been given to the approach of the social scientist rather than to that of the statistician, administrator, or personnel officer. Actions taken in selecting and assigning personnel, for example, directly affect most of the decisions discussed.

One frequently hears that "public health is people," that it is "everybody's business." If public health is so intimately concerned with people, then how well public health is succeeding in its programs may depend on how well our programs are wrapped around people—their needs, their wants, their hopes. The approaches I have been discussing are the types of approaches which are useful in determining whether we are wrapping our programs around people or whether we are attempting to wrap people around our programs.

Through applying the tools of measurement, we can obtain data for the guidance of program improvement as the program continues. We must always be aware, however, that the data obtained in evaluating program progress are not valid for determining whether or not the broad goals of the program are achieved. For this purpose, sound studies of program achievement are essential. Both evaluation of program progress and evaluation of program achievement are essential to satisfy the two major purposes of evaluation—guidance for the conduct of program activities and objective estimates of achievement. Neither can be neglected if we are to make certain that our efforts and money are well spent.

An Outbreak of Salmonellosis Traced to Watermelon

By GILBERT E. GAYLER, M.D., ROBERT A. MacCREADY, M.D., JOSEPH P. REARDON, M.D.
and BERNARD F. McKERNAN, M.D.

WATERMELON as a vehicle in salmonellosis outbreaks is not thought to be an important public health hazard, but its possible danger should be recognized by public health officials.

This paper describes an outbreak of salmonellosis spread by watermelon. To our knowledge, its previous occurrence has never been reported. Indeed, while meat products, fowl, eggs, salads, and, occasionally, pastries are common vehicles of *Salmonella* infection, fruits are seldom implicated.

Epidemiology

Early in June 1954, 17 cases of gastroenteritis occurred in Upton, a rural town in Massachusetts. The 17 cases involved 5 family units, with ages of the patients varying from 2 to 80 years. The patients all had initial symptoms on the same day or the next day. The symptoms were those of nausea, vomiting, abdominal

cramps, diarrhea, and fever. The diarrhea in a number of the patients was unusually severe; it lasted for several days with resulting dehydration and prostration. The 80-year-old patient died of a complicating tibial artery thrombosis, and 1 of the 2 secondary cases of the outbreak occurred in the patient who shared the hospital room of this patient.

None of the 5 family groups had any apparent connection with one another. The only connection they had in common was the purchase of sliced watermelon from the same supermarket in the neighboring town of Milford. Symptoms began in each case 12 to 24 hours after the ingestion of the watermelon.

At first, watermelon appeared to be an unlikely vehicle for the infective agent of the outbreak. However, in 3 of the family units, 1 or 2 members or guests did not eat the watermelon. In each instance these individuals only were not ill. One member of a family ate sparingly of the melon and was only slightly ill. There was, therefore, apparently complete association between the eating of the melon and becoming ill afterward.

The market where the melons were bought was new and clean. The watermelons, which had been on sale for several days before the outbreak, were kept on an open counter. The melons were sold whole or sliced, and the sliced pieces that were awaiting sale were covered with wax paper.

Of the 3 watermelon samples submitted for

Drs. Gayler, MacCready, and Reardon are members of the Massachusetts Department of Public Health. Dr. Gayler is district health officer; Dr. MacCready is assistant director, biologic laboratories, and in charge of the diagnostic laboratory; Dr. Reardon is epidemiologist, division of communicable diseases. Dr. McKernan is a practicing physician in Upton, Mass.

examination to the health department laboratory—1 from each of 2 families and 1 from the supermarket—salmonellae were recovered in pure culture in immense numbers from the watermelons from both homes but not from the market watermelon. Stools were submitted from 9 of the 17 individuals who were ill. All were positive for salmonellae.

No enteric organisms were recovered from the knife used to slice the watermelons in the store, but salmonellae were recovered from the shelf where the knife was stored when not in use. However, no evidence of rodents could be found in the store, and traps especially set caught no animals. No enteric organisms could be recovered from the three clerks involved in slicing the watermelons; so far as could be ascertained, none of the clerks had had a recent enteric illness.

The Species *S. miami*

All of the salmonellae recovered were typed at the National Salmonella Center at the Beth Israel Hospital in New York, which classified them as *Salmonella miami*.

S. miami has been reported by Galton and Hardy as common in Florida (1, 2). They found this organism to be the cause of a food poisoning outbreak where contaminated pickle served in a restaurant was the disseminating vehicle. At various times they recovered it also from dogs, hogs, chimpanzees, and fowl. Although *S. miami* has been reported frequently in the other southeastern States as well as Florida, it is relatively rare elsewhere. It was, however, recovered in Massachusetts from 9 cases of gastroenteritis that occurred in July 1953, chiefly in the metropolitan Boston area. No definite connection between the cases could be discovered at the time, and we can only speculate as to their possible source.

Since the grower's label pasted on the outside of the watermelons indicated the fruit in the present outbreak came from Florida, and since *S. miami* is widespread in Florida (2), it seems reasonable to postulate that the organism may have come with the fruit from that State, rather than from some case or carrier within the store, where evidence of a human or animal source could not be found.

Some Speculation

How the individual watermelons became contaminated is, of course, an interesting question. On the supposition that the outside of the melon might, while in the field in Florida, have become contaminated with fecal material containing the organism and that the inside of the melon might have become contaminated only when the fruit was sliced before sale in the supermarket, we conducted a simple experiment at the diagnostic laboratory of the Massachusetts Department of Public Health.

In the experiment, the outside of a watermelon was swabbed with a dilute suspension of the *S. miami* organism, and then the watermelon was sliced with a clean knife. Cultures made from the cut surface, immediately and also after a few hours, each resulted in a few colonies on bismuth sulfite, but cultures made from the cut surface the following day, with the fruit remaining at room temperature in the meantime, resulted in innumerable colonies on bismuth sulfite. This would suggest that a knife by cutting through a watermelon that was contaminated on the outside with *S. miami* certainly could inoculate the watermelon so that the organisms would multiply upon the cut surface, under conditions prevailing in the supermarket where the melons were sliced for sale.

It was found also that a knife contaminated with a dilute suspension of *S. miami* could similarly inoculate a clean watermelon effectively. Thus, infection could be spread from melon to melon whenever the knife was not washed between cuttings.

Quite another method of contamination appears equally possible. The practice of injecting water into watermelons in this country, as well as in Asia, in order to increase their market weight, has been divulged on good authority. Obviously, contaminated water injected through clean watermelon surfaces, or clean water injected through contaminated watermelon surfaces could infect a number of melons.

Either of these means by which the melons could have become infected is, of course, hypothetical since the actual mechanics of the outbreak can hardly be proved. It does seem likely that the original source of salmonellosis was in

Florida where the melons were grown. In view of the huge number of watermelons sold in the market without previous reports of salmonellosis outbreaks, unless such outbreaks have escaped detection in the past, it does not appear that watermelons, whole or sliced, are a significant public health hazard, but they should be recognized by public health officials as a possible danger.

Summary

An outbreak of gastroenteritis caused by *Salmonella miami* is described. There were 17 primary cases among 5 families and 2 secondary cases.

The only article of food in common was sliced watermelon which had been purchased from the same market. Symptoms occurred 12 to 24 hours after the ingestion of the melon. *S. miami* was recovered from the sliced melon in 2 of the homes, from all of the stools submitted, and from the shelf in the store where the slicing knife was kept.

No evidence of human or animal source could be found in the store.

The melons were obtained from Florida, where *S. miami* is common, and the original

contamination of the melons may have occurred in Florida. Possible mechanics of the contamination of the watermelons are discussed.

. . .

Since writing this paper we have been informed of a similar outbreak of salmonellosis which occurred in Rochester, Minn., in August 1950. There were 6 cases in 2 families.

Each family had purchased half of a watermelon from the same roadside stand on the same day. Salmonella bareilly was cultivated from the remaining portions of the watermelon consumed by both families. Both specimens were heavily loaded with salmonellae. Only one stool specimen was submitted for examination, and this was negative for enteric organisms.

The outbreak was not reported in the medical literature.

Training in Rehabilitation

An intensive training course in methods and concepts of rehabilitation will be given at the University of California at Los Angeles, April 25-30, 1955, under the joint sponsorship of the university and the Office of Vocational Rehabilitation, Department of Health, Education, and Welfare.

Designed to enable participants to serve as leaders in the advancement of coordinated services for disabled persons, the course is offered for the following rehabilitation supervisory personnel: physicians, nurses, physical therapists, occupational therapists, rehabilitation counselors, and social workers. Participants will be selected on the basis of leadership responsibility in key positions in five western States, but general sessions will be open to all interested members of the various professions.

Further information may be obtained from: Dr. W. A. Selle, Chairman, Committee on Rehabilitation, Department of Biophysics, School of Medicine, University of California Medical Center, Los Angeles 24, Calif.

Unexpected advantages followed application of Iowa's new hog feeding law, aimed at zoonoses. Lower death losses and heavier herds on a given volume of feed were bonuses in a public health program.

Garbage Cooking in Iowa

By E. ROBERT BAUMANN, Ph.D., and M. T. SKODJE

AN IOWA LAW, which became effective June 1, 1953, requires the cooking of garbage fed to animals. The Iowa Department of Agriculture has the responsibility for enforcement. Regulations issued by the department state that garbage to be fed to swine in the State of Iowa shall be cooked or heated to 212° F. for 30 minutes by one or more of the following methods:

- A. Wet steaming or boiling in an open vat.
- B. Dry steaming or boiling in a jacketed kettle.
- C. Steaming in a pressure cylinder.
- D. Steam boilers.
- E. Direct heating over an open fire.

A survey of the garbage-cooking installations in Iowa was made recently by Iowa State College personnel with the cooperation of the U. S. Bureau of Animal Industry. The survey pro-

vided information on the types of cooking methods being used in the field. This information was used as a basis for the selection of equipment to be used in laboratory studies that the engineering experiment station and the division of veterinary medicine at Iowa State College are now conducting on methods of cooking garbage. The project, titled "The Survival of Swine Disease Organisms in the Heat Treatment of Garbage," is being conducted under a grant from the National Institutes of Health.

Garbage Feeders in State

Up to June 1, 1953, when the law went into effect, there were more than 400 garbage feeders in the State. Most feeders ceased feeding for several probable reasons: First, little was known about methods of cooking garbage; second, many feeders doubted that garbage could be cooked economically; and third, many feeders doubted that the cooked product would be eaten by the hogs. The number of feeders operating under the new regulations has gradually increased until by July 1, 1954, 13 months later, 60 garbage feeders were again feeding hogs. Since most garbage feeders in Iowa usually feed garbage as a sideline, they are comparatively small-scale operators.

As of July 1, 1954, 52 private feeders had been licensed to process garbage for hog food.

Dr. Baumann, formerly research associate in sanitary engineering at the University of Illinois, Urbana, has been associate professor of civil engineering, Iowa State College, Ames, since 1953. Mr. Skodje is associate in civil engineering at the same college. Both are on the staff of the Iowa engineering experiment station. Dr. C. W. Brown, Charles Cumpston, and A. D. Jewell of the U. S. Bureau of Animal Industry assisted in this study.

In addition to the private feeders, there were 8 garbage-processing installations located at Federal and State institutions, which do not require a license.

All of the garbage feeders collect, process, and feed commercial garbage, collected principally from restaurants, hospitals, hotels, food markets, and dormitories. Two feeders collect residential garbage and feed some of it along with the commercial garbage. Some handle a restricted type of garbage. Two feeders handle chiefly bakery-dough wastes, and two handle beef or swine offal and bones. The fuel costs vary from a negligible amount for the operator using scrap wood and tires to from 0.5 to 1.5 cents per hog per day for those operators using oil, kerosene, or bottle gas for fuel.

All of the feeders interviewed indicated that they were satisfied with the requirement that all garbage must be heat treated before feeding. They believed that feeding cooked garbage produced unexpected advantages in lower death losses and an ability to increase their herd size on the same amount of garbage.

On July 1, 1954, 5,275 swine were being fed in Iowa on heat-treated garbage. The average herd was about 88 swine; the largest herd of swine was 579 head, and the smallest was 26. During a normal month, about 1,000 garbage-fed hogs are sent to market from these farms. During the maximum month 1,898 garbage-fed hogs were marketed.

A summary of the various types of garbage-cooking methods used in the State is given in the table.

Two private feeders have not been classified

as to method of cooking. One has not yet installed heat-treatment equipment, and his license is pending. The other is cooperating in the study at Iowa State College and is using all the types of cookers listed in the table. His equipment, therefore, would not be indicative of garbage cooking in Iowa.

Because few commercial cookers were available when the cooking law became effective, 70 percent of the cookers now in use are homemade. Sixty-four percent of the Iowa installations are direct-fired cookers, and of these 66 percent are homemade. The usual direct-fired cooker utilizes a flame in direct contact with the outer surface of the cooking vessel in which the garbage is contained. Most of the 25 homemade installations are simple, covered, rectangular or cylindrical tanks mounted on an earth, brick, or concrete block firebox. The farmer feeder usually utilizes oil as a source of heat, but the nonfarmer feeder, usually located on or near dumping grounds, uses waste tires or wood for fuel. None of the homemade installations visited was designed to use fuel economically.

Direct-Fired Kettles

All 13 commercial direct-fired kettles listed in the table utilize bottle gas, oil, or kerosene for heat. Frequently, the commercial direct-fired cooker is designed as a compact, trailer-mounted, double-walled tank heated with one or two burners. The hot flue gases pass back and forth through the space between the inner and outer walls of the cooker and heat the garbage effectively. Of the 38 direct-fired kettles, only

2 commercial, trailer-mounted cookers have mechanical stirrers to mix the garbage and assure even cooking. Observations and experiments by the authors both in the laboratory and in the field have verified the conclusion of the operators that the mixing devices provided are ineffective.

Direct-fired cookers normally have the disadvantage of high heat concentrations at the interface between the garbage and the garbage container. Unless the cooker is well designed, much of the heat is lost through the stack. Some of the advantages of this type of cooker are the rapid heating and the control of the moisture content of the garbage. The maximum amount of water in the garbage can be kept at a minimum with this method. The minimum amount of water, however, is fixed by the characteristics of the cooker and the garbage and is the amount of water necessary to prevent scorching or burning. Although the average commercial garbage is quite wet, all of the Iowa direct-fired installations require that some water be added to the garbage before cooking. Some operators have found it best to heat the water in the cooker before adding the garbage. This helps to prevent scorching or burning.

Direct Steam Injection

Direct steam injection is the second most common method of cooking in Iowa, and 29 percent of all installations are of this type. As the name implies, live steam is injected directly into the garbage to raise it to the boiling temperature. Most of the steam-injection installations are listed as homemade, since the cooking tanks or vats were designed by the operator and fabricated locally. All but one of the installations use commercial steam boilers for steam production. In this one a homemade, closed, cylindrical tank is used for a boiler and the fuel used is wood or old tires. No safety devices are provided at the boiler, and the authors regard this as very dangerous.

The tanks or vats in which the garbage is heated are usually rectangular, truck-mounted units equipped with a removable cover. Tanks are similar but not uniform in construction, and vary in capacity from about 60 cubic feet to 200 cubic feet. Most tanks have metal covers for

heat conservation, although a few have canvas covers.

Two types of racks are in use for distributing the steam throughout the garbage. The first is a removable rack, which is a horizontal grid of pipes with a central steam-pipe header and several transverse laterals. Vertical lances of small diameter pipe are connected to the laterals. The lances are so located that they are spaced uniformly throughout the tank during cooking. Small holes in the vertical pipes permit the steam to flow into the garbage. This pipe rack is lowered into the garbage until the vertical lances penetrate to the bottom of the load. Most operators have found the lance-type pipe rack unsatisfactory because of the labor required to insert the lances into the garbage and because of the uneven steam distribution caused by the steam following the path of least resistance, along the side of the lances.

Although two installations still utilize the vertical lance-type rack, most feeders have converted to the second type of rack used in Iowa. This is a horizontal pipe rack permanently installed in the bottom of the cooking tank. Most installations use a header pipe across the front end of the tank and smaller lateral pipes running lengthwise of the tank. Numerous small holes drilled into the laterals are used for steam distribution. Lateral spacing, hole size, or hole spacing are not uniform. Only two installations are known to provide blowoff valves for clearing the steam lines of condensate and garbage liquor.

Direct-steam-injection cookers provide for maximum heat transfer from the steam to the garbage. A low overall thermal efficiency may sometimes be found, however, if the steam boiler or generator has not been well engineered. Steam produced by the common boiler or low-pressure generator may be a mixture of dry steam vapor and hot water. A boiler or generator in a good garbage-cooking installation should produce steam of high quality. The quality of steam is the percent by weight which is actually dry steam vapor.

The amount of steam required to cook a load of garbage depends upon many factors, including the amount of garbage in the load, the amount of water in the garbage, the temperature of the garbage and the surrounding air, the

physical nature of the garbage and cooker, and the quality of steam used. The hot water included in the steam mixture does not contribute any effective heat during cooking. A possible disadvantage of this method of cooking in colder climates is the large amount of water added to the garbage in the form of condensed steam. None of the feeders interviewed during the recent tour of Iowa, however, found any fault with the amount of water added using this method.

At least two feeders using the direct-steam-injection method of cooking attempted to use commercial steam cleaners for producing steam. The steam produced was found to average about 10-15 percent dry steam and 85-90 percent hot water. The excessive quantities of water added to the cooked garbage by using this low-quality steam forced the abandonment of these steam-producing units. All of the Iowa feeders using direct steam injection operate steam boilers whose steam quality is usually over 90 percent.

Dry-Steam Coils and Jackets

Dry-steam heating is the term sometimes applied to the method of heat application in which the steam does not come into direct contact with the garbage. Instead, the steam transmits its heat through an inner wall of a steam jacket or through a heating coil placed in the load of garbage. Five percent of all Iowa installations are of this type. An advantage of this method over the direct-injection method is the heat economy brought about by mixing the hot steam condensate with the cold make-up water and returning it to the boiler. As in the direct-fired method, Iowa feeders find it necessary to add water directly to the garbage to prevent the garbage from scorching. For this reason, one operator has constructed a combination truck-mounted, dry-steam and direct-steam-injection cooker. A false bottom about 2 inches deep has been built in the bottom of a rectangular tank. Permanently installed vertical lances spaced uniformly around the periphery of the tank lead upward from the false bottom. The vertical risers contain small holes to permit the escape of some steam from under the false bottom into the garbage. The oper-

ator believes that the garbage can be cooked faster and with less added water; but temperature checks by the authors do not substantiate the operator's opinion.

One feeder in Iowa uses a wet-rendering pressure cooker. Operators of a sausage plant in Iowa are processing the offal from their animals and their death losses for use as swine feed in a vertical, wet-rendering cooker. The offal and bones are cooked under 75 pounds per square inch of steam pressure for 14 hours. The installation combines direct steam injection with cooking under pressure to produce an excellent homogeneous product. The cooker outlet is located on the bottom and opens over an open-top farm tank. The inlet is located at the top of the tank. The offal is raised to the inlet by means of a bucket hoist. The cooked offal is dumped directly into the farm tank. The resulting cooked mass is quite fluid and the liquid is decanted off the top of the tank before feeding. The residue is virtually all edible.

"Cold Spots"

Recently about one-third of the Iowa installations were visited by the authors. Most of the cookers examined were found to contain "cold spots" in the tanks or areas where the temperatures of the garbage had not reached at least 170° F. when the cooking was supposed to be complete. No field test other than the mechanical location of cold spots in the garbage has been used to determine whether or not the heat treatment has destroyed the swine disease organisms. Interpretation of the Iowa law is that such cold spots should be brought to a temperature of 212° F. for at least 30 minutes. The temperature of the garbage during cooking must be permanently recorded on an acceptable temperature recorder. The operators have been instructed to locate the temperature recorder at habitual cold spots rather than in "hot spots." Methods for controlling garbage cooking to assure more strict compliance with the heating requirements for destroying swine disease organisms are being evaluated at Iowa State College.

All of the cookers were judged to be adequate to bring the garbage to a boil, provided the operator will conscientiously gauge his opera-

tions by the cold spots in his equipment rather than the hot spots. Sanitary procedure in handling the raw and cooked garbage as well as general sanitation around the cooker and pens appears to be one of the most easily broken links in the defense against swine diseases. The average feeder needs to know and to be impressed with the possibility of infecting his animals as well as those of others by laxity in conforming with the sanitary regulations. Accordingly, the average installation feeding cooked garbage is inspected by State and Federal inspectors from 12 to 24 times during a year. The authorities in Iowa are continually working to raise the standards of sanitation at these installations. As a result, a number of the feeders who operate marginal installations are making plans to increase their investment to improve sanitation and the cooking operation and to reduce garbage handling.

Liquidation Costs

The costs of installing garbage cookers in Iowa have been estimated to range from \$50 to \$3,000. In most cases, little consideration was given to the labor involved in handling and transporting the garbage during and after cooking. As a result, the garbage frequently must be dipped from the cooking tank by hand and transported manually to the feeding troughs. An increasing number of cooking tanks are being provided with chutes and doors to reduce the handling of the garbage. None of the feeders use grinding equipment to provide a more uniform garbage particle size, even though ground garbage would be easier to handle, would pro-

vide for more efficient transfer of heat, and would perhaps make more of the garbage available to the swine. Only two operators make any attempt to agitate the garbage artificially during cooking to secure more even heat distribution. The cost of the treatment is more than offset by increased income from their herds, for the hogs prefer the cooked garbage to raw garbage and a much larger percentage of it.

Conclusions and Comments

1. The Iowa law requiring the heat treatment of garbage resulted in a drop in the number of garbage feeders from over 400 to 60 feeders. The number of feeders cooking garbage has increased steadily, however, during the last 13 months and may be expected to continue to increase.

2. A majority of the cookers are homemade installations which were not designed for maximum heating efficiency or for fuel economy. Commercial cookers are, however, becoming more popular.

3. The direct-fired cooker is used most frequently for cooking garbage. Direct-steam-injection cookers are also used and are becoming more popular.

4. All of the operators interviewed report that they have gained rather than lost under the new regulations.

5. Only 5,275 swine were being fed cooked garbage in Iowa on July 1, 1954. On January 1, 1955, there were 73 licensed feeders in Iowa, feeding cooked garbage to 8,236 hogs. Six Federal inspectors from the Bureau of Animal Industry are now active in Iowa.

Special reference is made to case confirmation studies on Rocky Mountain spotted fever and endemic typhus in Georgia and to effective tick control measures. McDuffie and Smith discuss tick control in further detail on p. 327.

The Status of Rocky Mountain Spotted Fever in the Southeastern United States

By JOHN E. McCROAN, Ph.D., RALPH L. RAMSEY, A.B., WILLIAM J. MURPHY, M.D., M.P.H., and
LILLIAN S. DICK, R.N., B.S.

ROCKY MOUNTAIN spotted fever is unique among the arthropod-borne diseases of man now or formerly endemic in the southeastern United States in that no reservoir host other than the tick vector appears to be required. Transovarian transmission occurs, and larvae, nymphs, and adults are all potentially capable of transmitting the infection. Presumably even the egg might infect if it were crushed on the unprotected skin. Nevertheless, extensive research on rickettsial spotted fever over many years has revealed no naturally infected animal in the United States. When the disease is experimentally transmitted to dogs and other mammals, the infection is frequently silent, and the only indication of inoculation is the develop-

ment of Weil-Felix and complement-fixing antibodies (1).

As is well known, the number of infected ticks in nature is subject to great variation but seldom has been found, even in highly endemic areas, to exceed 3 percent (1). Under ordinary circumstances the infection rate is usually of the order of one in many thousands.

In 1902 Wilson and Chowning (2) suggested that Rocky Mountain spotted fever was tick-borne and that the etiological agent was a protozoan. Subsequently Ricketts (3), Parker and his associates in the Rocky Mountain Laboratory of the Public Health Service at Hamilton, Mont., and many others worked out the etiology and epidemiology of the disease and many of the details of tick-host relationships. Man is merely an unusually susceptible bystander, who by occasional accident intrudes himself into the cycle as a very unsatisfactory host for *Dermacentor andersoni* in the western or for *Dermacentor variabilis* in the eastern United States.

Rocky Mountain spotted fever was first identified in the eastern United States in 1931 by Badger, Dyer, and Rumreich (4). Until 1940 it was believed that the eastern strains were less virulent than the Bitterroot Valley strains,

Dr. McCroan is assistant director, Mr. Ramsey is public health biologist, and Dr. Murphy is director, division of epidemiology, Georgia Department of Public Health. Miss Dick is assistant chief, Vector Borne Disease Unit, Communicable Disease Center, Public Health Service, Atlanta. This paper was presented at the 23d annual meeting of the Southern Branch of the American Public Health Association, St. Petersburg, Fla., April 21-23, 1954.

but in that year Topping and Dyer (5) reported the isolation of a strain, the W strain, from the Potomac Valley, which was in every way similar to the so-called Bitterroot strain. In 1941, in a note on the epidemiology of Rocky Mountain spotted fever, Topping (6) compared the existing data with regard to age and sex-specific morbidity and mortality from Montana and Idaho with that from Virginia and Maryland. Although he noted some interesting differences in attack rates, he showed that age-specific fatality was essentially the same in the east and the west. He also pointed out that *D. andersoni*, a parasite of large wild animals, occurs in greatest numbers at a distance from human habitation in sparsely settled areas while *D. variabilis* is sufficiently adapted to the dog to justify being named the American dog tick. This difference serves to explain the higher incidence of Rocky Mountain spotted fever among children in the east and among adult men who work in tick territory in the west.

Harrell (1) has assembled more recent and extensive data, shown in table 1, which is confirmatory of Topping's thesis. It will be noted that the fatality rates shown are almost identical for the east and the west. During the same period, 1939-46, Georgia had a fatality rate of 18.9 percent.

Comparison With Endemic Typhus

In introducing a comparison between Rocky Mountain spotted fever and endemic typhus, it is interesting to note that when the latter disease was first described in the United States, in 1913, by the late Dr. James E. Paullin (7) of Atlanta, existing epidemiological knowledge did not enable him to differentiate between the infection he described and Brill's disease, the separate etiology of which was first suggested by Zinnser (8) in 1934 and finally clarified by Murray and his associates (9, 10), in 1950 and 1951 as a result of post-World War II developments.

In contrast to Rocky Mountain spotted fever, endemic typhus, we now know, is well established in an abundant mammalian host, the domestic rat, which serves as the reservoir from which the infection is transmitted to man. The principal vector is *Xenopsylla cheopis*, the In-

Table 1. Rocky Mountain spotted fever cases and deaths—selected western and southeastern States, 1939-46¹

dian rat flea. Control efforts, which have been reasonably successful, consist first, of DDT dusting of rat harborages for the purpose of preventing the spread of infection from rat to rat and from rat to man and, second, of rat control measures (11).

A summary of more recent reporting of Rocky Mountain spotted fever in 10 southeastern States, as compared with typhus, is given in table 2. Certain of the data are of particular interest.

First, it will be noted that the southeast has accounted for about one-half of the reported cases of Rocky Mountain spotted fever in the United States during the 1949-53 period.

Second, these data show that typhus in the southeast has reportedly declined from two-thirds of the national total in 1949 to less than one-half the United States total in 1953.

Third, since 1952, more Rocky Mountain spotted fever than typhus has been reported.

Fourth, it appears that the States of the upper south—Virginia, Kentucky, Tennessee, and North Carolina—have a marked predominance of Rocky Mountain spotted fever over typhus and that typhus leads in the Gulf States and Georgia, while South Carolina is approaching a balance between the two diseases. The fatality rate for Rocky Mountain spotted fever in

Georgia during the total period 1939-53 was 18.1 percent, while the typhus fatality rate was 4.9 percent.

Case Confirmation Studies

Laboratory confirmation of reported Rocky Mountain spotted fever was undertaken in 1939 by the Georgia Department of Public Health in order to determine the true incidence of this disease in Georgia and has been continued to the present time. Confirmation was based on animal protection tests during the early part of the period covered by table 3 and upon complement fixation tests during recent years (see footnote 2, table 3). From the first, these studies have necessarily included cases of endemic typhus because of the similarity in etiology and clinical behavior of the two diseases. Moreover, the Weil-Felix reaction is common to both and not infrequently a case diagnosed as typhus on the basis of a positive Weil-Felix test has been shown to be Rocky Mountain spotted fever. On the other hand, all typhus confirmations recorded from Georgia prior to 1945 were obtained on patients suspected of having Rocky Mountain spotted fever.

A parallel typhus case investigation program came into existence as a result of the reduction in funds available for typhus control. For

planning purposes, it became essential to know whether reported typhus cases gave a true picture of the incidence of this disease.

It will be noted from table 3 that although typhus showed a steady decline after 1945, the incidence of Rocky Mountain spotted fever continued at a comparatively high level through 1949. Much of the decrease in typhus was undoubtedly the result of the DDT and rat control programs (11), and since 1946 the incidence of Rocky Mountain spotted fever has been influenced by the eradication of several suburban foci around Atlanta (15). After about 1949 or 1950, however, the decline in the reported incidence of the two diseases has been affected by the availability of drugs effective in the treatment of rickettsial infections.

The antibiotics—terramycin, aureomycin, and chloramphenicol—produce a marked effect on the clinical course of the two infections. Studies in Georgia and elsewhere also show that these drugs influence the appearance of Weil-Felix and complement-fixing antibodies (14, 16). It is probably safe to say that a relatively small percentage of Rocky Mountain spotted fever and typhus infections now develop to the point of complete diagnosis and reporting.

The notation used in table 4 has no mathematical basis. It is an attempt to show together the Weil-Felix (left) and complement fixation titers (right) on individual specimens. As

¹ Includes only cases reported through usual channels to the Georgia Department of Public Health. Does not include 210 typhus cases picked up in epidemiological investigations made by Hill and associates (12, 13) and by Stewart and Hines (14) in Brooks, Grady, Thomas, and Decatur Counties, Ga., during the period January 1945-January 1953.

² Data for 1939-46 are based upon case histories and laboratory confirmations obtained by Dr. T. F. Sellers, then director of laboratories, Georgia Department of Public Health (now, director of the department). Typhus cases confirmed during this period were only in those patients suspected of having Rocky Mountain spotted fever. In 1939-40, confirmation was by animal protection tests carried on by the Typhus Research Unit of the Public Health Service at Albany, Ga. From 1942 to 1946, confirmations were based on complement fixation tests performed at the National Institutes of Health. From 1946 to date, complement fixation tests have been carried on in the Chamblee, Ga., and Montgomery, Ala., laboratories of the Communicable Disease Center, Public Health Service.

will be noted, the development of Weil-Felix antibodies is somewhat delayed under the impact of antibiotic therapy while complement-fixing antibodies may not appear for months, and the final titer may be considerably reduced below the levels formerly obtained. The exact interval of delay cannot be stated since specimens were not obtained with this purpose in view. Terramycin, aureomycin, and chloramphenicol appear to manifest an effect in the order named. Penicillin has no effect on either Weil-Felix or complement fixation titers and no effect on the course of the illness.

Five of the nine cases of Rocky Mountain spotted fever confirmed in 1953 were originally reported as typhus. One of the confirmed typhus cases was reported as Rocky Mountain spotted fever. Five of the 29 unconfirmed typhus cases were classified as presumptive, but 24 of these cases remained diagnostic problems even after prolonged study.

Various possibilities suggest themselves with regard to these cases, but it should be recalled that in Georgia almost all "reported" rocky

Mountain spotted fever and typhus are picked up by query as the result of positive Weil-Felix examinations done in health department laboratories. The difficulty is therefore apparently serologic, arising from the suppression of rickettsial infections by antibiotics referred to previously.

Fortunately, followup specimens can be obtained on the majority of Weil-Felix positive cases, and on cases on which complement fixation tests have been requested if the surveillant agency is prepared to assist, either directly or through local health departments, in obtaining specimens. It is also necessary in requesting specimens to persevere to the point at which persistence ceases to be a virtue.

The problem of obtaining convalescent and postconvalescent specimens is difficult indeed when the initial Weil-Felix reaction is negative. Although the case may be diagnosed as spotted fever or endemic typhus, second specimens are seldom forwarded unless the patient continues to be ill after treatment with broad spectrum antibiotics. This leaves the laboratory in a

quandary since it appears impractical to catalog and hold negative serums on suspected cases indefinitely on the assumption that a later specimen may show a rise in titer. Negative specimens are now retained for approximately 1 month in the laboratories of the Georgia Department of Public Health.

Tick Control Methods

During recent years the possibility of using certain compounds as tick repellants has been investigated by several workers. These compounds have been applied as dusts and aerosols to skin and clothing and as solutions or emulsions to clothing.

Despite statements in the literature which imply otherwise, roadside and pathside control of *D. variabilis* and, in our experience, of *Amblyomma americanum* is so easily obtained with insecticides that chemical control has very definite application in inhabited areas of high Rocky Mountain spotted fever hazard or even where tick annoyance is the only problem. Dust, sprays, mists, and possibly even fogs, with several of the older insecticides are reasonably effective. It is conceivable that some of the newer insecticides, for example dieldrin (17), would be even more useful, but we have had little occasion to try them in Georgia.

Interest in the control of Rocky Mountain spotted fever in Georgia reached a high point in 1945 following the occurrence of 24 clinical cases, 17 of which were serologically confirmed, in the semiurban regions of De Kalb and Fulton Counties (Atlanta) during the period 1939-45. In 1946, when work was begun in the Alexander Estates section of De Kalb County, the most seriously affected area, the entire section was beginning to drop in the economic scale despite its being conveniently located, already subdivided, and having city conveniences available. When no Rocky Mountain spotted fever cases occurred during the next 2 years, the situation changed completely. By 1951 homes had been erected on every lot available for construction, and a shopping center had developed in the area.

The following insecticides have been used successfully in tick control:

DDT, at the rate of 2.5 lb. of actual insecticide per acre for dusts, sprays, mists, and fogs. If rosin-DDT emulsion is used in a good mist machine, 1.5 lb. of DDT per acre gives good residual control of *D. variabilis* for an entire tick season. No burning of vegetation was noted when rosin emulsion was applied along roadsides.

Chlordane, at 1 lb. per acre, is almost as effective as DDT in dusts, sprays, mists, and fogs.

Table 4. Weil-Felix/complement fixation results in 12 patients diagnosed as having Rocky Mountain spotted fever and treated with antibiotics, 1953-54

NOTE: Dash (—) means test not done or results unknown, and N means negative.

Benzine hexachloride, at one-half pound per acre, was inferior to DDT and chlordane. It gave best results when applied as a mist.

Methoxychlor, at 2.5 lb. per acre, gave good immediate control but broke in less than 1 month.

Smith, Cole, and Gouck (18) pointed out in their classic study on the American dog tick that this tick (*D. variabilis*) tends to collect along roadsides and paths. This fact has occasioned the interest of Knutson (19) and others in the use of very narrow dust or spray barriers along roadsides. Glasgow and Collins (20) report use of DDT dust at a rate of 1 lb. per acre in a 4-foot wide strip. Knutson used a low pressure, low gallonage sprayer to apply 1 lb. of DDT per acre in a strip 6-8 feet wide. In a single narrow barrier dust experiment repeated by us, very good results were obtained.

Nevertheless, these methods afford protection only to persons or animals who stay in the road and do not venture across the barrier. Children and dogs have a tendency to go to the ticks even though the ticks cannot come to them. For this reason, and also because power equipment, particularly mist generators, will give excellent coverage of a 50- to 100-foot strip along roadways, a wider swath has been used by us. Results have been equal to those described in narrow barrier experiments, the immediate knockdown is more extensive, and the residual effect is probably as great although no one has had an opportunity to make a comparative study. In addition, McDuffie and associates (21) have reported data which imply that reinfestation tends to occur more slowly when the treated area is large.

Wide-strip spraying is an easier technique in use since one can "offset" the line to be treated and operate from the roadway. Narrow barrier application with power equipment runs afoul of telephone poles, trees, benches, signs, and other obstacles. In wide-strip application it is convenient to apply insecticide in two runs, with the spray or dust aperture pointed at the road edge on one trip and set for maximum distance on the second.

Summary

Rocky Mountain spotted fever is a disease of measurable though not great public health im-

portance in the southeastern United States. It ranks with or exceeds endemic typhus as a cause of morbidity and mortality in all the States of the area (Alabama, Florida, Georgia, Kentucky, Louisiana, Mississippi, North Carolina, South Carolina, Tennessee, and Virginia).

Reporting of all rickettsial infections has been adversely affected by the availability of effective chemotherapeutic agents. The rickettsial infections are so well masked by antibiotics that many cases are aborted and diagnosis with complete laboratory confirmation is a rarity. Development of complement-fixing antibodies is delayed sometimes for 6 or more months. Confirmation of diagnosis in recent years has been achieved largely as the result of epidemiological followup of cases by public health agencies.

Tick repellants have been developed to a point which makes their use practical by persons working or playing in infested areas. Chemical control of ticks in thickly settled Rocky Mountain spotted fever foci has been satisfactorily achieved. Barrier spraying along roadsides is sufficiently simple and effective to merit consideration wherever ticks annoy enough people to make tick control economically acceptable.

Blind Vending Stand Operators

Nearly 1,670 blind vending stand operators and their employees earned approximately \$4.8 million during fiscal year 1954, the United States Office of Vocational Rehabilitation in the Department of Health, Education, and Welfare reported in January. These are the highest net earnings ever recorded by the blind men and women who operate vending stands under the Randolph-Sheppard and State laws.

In fiscal year 1953 net earnings for these businesses were approximately \$4.5 million.

This year's record was made by the blind operators with the aid of 272 blind and 629 sighted employees. The blind operators averaged \$2,200 each. Virtually all blind persons in the vending stand program were prepared and trained by their State vocational rehabilitation agencies.

Nearly 1,600 stands are currently operated under the Randolph-Sheppard Act, 573 of these being on Federal sites. Under recent amendments to the act, vending stands can be established on all types of suitable Federal property—in national parks, for instance. In the past this authority has applied only to federally owned or leased buildings. The Federal law has always required that preference be given to qualified blind persons as operators of stands on Federal property.

It is estimated that there are 308,000 blind persons in the United States today. Of this number, only about 8 percent are employed in all types of occupations. Experience in the rehabilitation of disabled individuals has indicated that about 25 percent of those disabled by blindness can be rehabilitated into gainful employment.

or emulsion of the repellent by dipping the garment into it or by pouring on enough to saturate it.

Rayon and nylon fabrics should not be treated with repellents. Nylon is nonabsorbent and will not retain enough repellent to be effective, and rayon is injured by some repellents.

A 5-percent solution or emulsion of the repellent will give a deposit of about 2 grams a square foot on denim, ordinary cotton khaki, or light wool clothing. About 3 pints is required to thoroughly wet a complete outfit of socks, shirt, and trousers of these fabrics. A smaller amount is sufficient for lighter fabrics.

Acetone and dry-cleaning solvents are suitable for use in impregnating both cotton and woolen clothing. Slightly less than an ounce of repellent to a pint of these solvents will make about a 5-percent solution. One ounce of repellent, 1 pint of water, and 2 ounces of a good emulsifier, such as Tween 80 or Triton X-100, or 1 ounce of laundry soap, will make an emulsion containing about 5 percent of repellent. The laundry soap should first be dissolved in the water; then the repellent should be added slowly to the mixture while it is being stirred vigorously by hand or with a household mechanical mixer. The synthetic detergents in common use for dishwashing and other household cleaning are not suitable for making emulsions, but most of the soaps are satisfactory.

After clothing has been wetted, it should be wrung out by hand, hung up outdoors, and allowed to dry thoroughly before it is worn. Properly treated clothing will provide good to excellent protection against ticks, as well as chiggers and mosquitoes, for several days to a

week if it is not subjected to wetting by rains or wading in streams or lakes. Clothing should be thoroughly washed and re-treated at weekly intervals or before each infrequent excursion outdoors.

Relationship of Industrial Carcinogens to Cancer in the General Population

By PAUL KOTIN, M.D., and W. C. HUEPER, M. D.

AWARENESS of environmental cancer and recognition and acceptance of the extent of this problem are increasing in the United States.

A rapidly growing accumulation of evidence suggests that industry-related or occupational cancer hazards carry as a corollary a similar, though diluted or attenuated, hazard for the general population. The industrialization of society during the past half century has resulted in certain new socioeconomic phenomena, one of which has been the concentration of population in close proximity to industrial sources of environmental pollution. This concentration

of population and the recent advent of the atomic age, the era of synthetics, and the petroleum economy, when combined with epidemiological observations, indicate that a general population hazard is of more than theoretical significance.

This hazard may be evaluated by two complementary methods of study. The first is an epidemiological-statistical analysis of both occupationally and environmentally exposed persons, using morbidity and mortality data; the second is the experimental assessment of the carcinogenicity and carcinogenic potency of known and suspected materials in the environment. The summation of both approaches often permits of conclusions impossible with either approach alone. Questions as to the value of experimental studies may be disposed of on the basis of the knowledge that confirmed or highly suspect environmental carcinogens have been proved to be carcinogenic for appropriate animal species. For those substances in which carcinogenicity is still lacking suggestive confirmation, experimental studies have been essentially unsuccessful in terms of tumor production.

In those other instances in which proved experimental carcinogens have thus far failed to demonstrate an analogous human tumorigenic response, it must be remembered that latency or the initiation-promotion-tumor development sequence in human beings is a long one and substances such as plastics (1), selenium (2),

Dr. Kotin is assistant professor of pathology, University of Southern California School of Medicine, Los Angeles, Calif., and principal investigator on a current study of the biological effects of atmospheric pollution. Dr. Hueper is chief of the Environmental Cancer Section, National Cancer Institute, Public Health Service. He is consultant on environmental cancer for the Department of Labor and chairman of the Committee on Cancer Prevention, International Union Against Cancer.

This paper was presented before the occupational disease sessions of the International Congress of Clinical Pathology, Washington, D. C., September 8, 1954. Part of the work reported was supported by a grant from the Field Investigations and Demonstrations Branch, National Cancer Institute.

NOTE: In these communities the pasteurized market milk shows a 90-percent or more compliance with the grade A pasteurized milk requirements, and the raw market milk shows a 90-percent or more compli-

ance with the grade A raw milk requirements, of the Milk Ordinance and Code Recommended by the United States Public Health Service.

Note particularly the percentage of the milk pasteurized in the various

communities listed. This percentage is an important factor to consider in estimating the safety of a city's milk supply. All milk should be pasteurized, either commercially or at home, before it is consumed.

Arrest and cure of cervical cancer may be achieved in many cases by recognizing malignant cells before they become invasive. Described is the exfoliative cytology technique of screening patients for early and unsuspected uterine cancer.

Uterine Cancer Case Finding by Vaginal Cytology

—Memphis and Shelby County, Tennessee—

By JOHN E. DUNN, JR., M.D., M.P.H., and DOUGLAS H. SPRUNT, M.D.

EXFOLIATIVE CYTOLOGY as a technique for recognizing cancer cells shed or abraded from epithelial surfaces has greatly facilitated the recognition of carcinomata before they become invasive, particularly carcinoma of the uterine cervix. Such a carcinoma is not apparent by its mass or by its surface, and on visual inspection, it is not distinguishable from normal or benignly altered epithelium. Discovery, therefore, at this stage is largely dependent on recognizing suspicious cells sampled from epithelial surfaces. Blind sampling of larger surfaces can be accomplished more efficiently by smear than by biopsy, although this fact has no bearing on the relative merits of the two procedures for establishing a final diagnosis.

Dr. Dunn is a field investigator with the Field Investigations and Demonstrations Branch of the National Cancer Institute, National Institutes of Health, Public Health Service, detailed to the California State Health Department, Berkeley, Calif. Dr. Sprunt is chief of the division of pathology and microbiology and director of the Institute of Pathology, University of Tennessee, Memphis.

The cytological technique in finding cases of cervical carcinoma presents some practical difficulties, but these are not insurmountable. In Memphis and Shelby County, Tenn., an area with a population of about 165,000 adult females, a uterine cancer case-finding study was begun in August 1952 to be continued for a 3-year period, or until all women who are participating have had an opportunity to have three successive examinations at yearly intervals.

One of the objectives of the study is to determine age-specific incidence and prevalence rates for carcinoma in situ and for presymptomatic carcinoma of the cervix. Because carcinoma in situ of the cervix is frequently present in younger women, all females aged 20 years and over are offered the opportunity for cytological examination.

Although the original technique for cytological examination was based on examination of the exfoliated cells in vaginal pool specimens (1), most cytology laboratories find it expedient to examine a specimen taken directly from the cervix only or a cervical specimen in conjunction with the vaginal pool specimen. In this study, vaginal pool specimens are used exclusively in initial screening, since they can be taken by personnel who are not physicians.

Organization of the Study

Specific plans for implementing the project were developed after the Memphis and Shelby County Medical Society had endorsed preliminary plans. The cytology laboratory is equipped and staffed by the National Cancer Institute of the Public Health Service. The division of pathology and bacteriology of the University of Tennessee furnishes space, supervises the operation of the project, and examines biopsy specimens from indigent patients. With the cooperation of the other pathologists in this region, this division sees all other biopsies recommended because of cytology findings.

A policymaking committee composed of the organizations participating and cooperating in the study includes representatives of the divisions of pathology and bacteriology and of obstetrics and gynecology of the University of Tennessee, the Memphis and Shelby County Health Department, the Shelby County Medical Society, the Bluff City Medical Society of Negro Physicians, the Shelby County Unit of the American Cancer Society, and the Public Health Service. The general plan of the study was approved by this committee, and in July 1951 preparations were begun to put the project into operation. A year was allowed for establishment of the cytology laboratory and the training of personnel.

Cytology Laboratory

Staffing the cytology laboratory and training technicians to handle the anticipated volume of 400 cytology specimens a day was the first step in organizing the project.

The laboratory staff is composed of a pathologist, a chief technician, 3 secondary screeners, and 12 primary screeners. The primary screeners work in groups of 4 under a secondary screener, who is responsible for supervising and checking their work. The 3 secondary screeners are supervised and their work is checked by the chief technician. Final review and interpretation of suspicious and positive slides are the responsibility of the pathologist.

One additional technician examines all cervical specimens when these are requested as repeat examinations. We believe that this is

important, since a smear from the cervix has so many more cells than a smear from the vaginal pool that a technician shifting from the examination of one type of specimen to the examination of the other is likely to become inefficient in both procedures.

Training of the staff was begun in July 1951. Three technicians who had had experience in cytology screening in a Public Health Service laboratory and one technician who had had training in the division of pathology and bacteriology of the University of Tennessee formed the nucleus of the staff. A physician with some training in pathology and with experience in cytology was also available for training and eventual supervision of the cytology laboratory.

Because additional technicians were not available, recent college graduates were interviewed, and 12 were selected as trainees. After a period of preliminary training, three of the best qualified technicians were sent to the cytology laboratory of the Vincent Memorial Hospital in Boston for additional training for supervisory positions. This laboratory uses vaginal pool specimens exclusively.

The cytology laboratory supplies the physicians of the community with materials for taking specimens from their private patients, collects the specimens periodically, and replenishes supplies of materials.

The amount of information which physicians are requested to submit to the laboratory with specimens is kept to a minimum: name, age, race, and home address; age at marriage; pregnancy history—age at first and at last pregnancy, number of pregnancies, and date of last menses; history of vaginal bleeding; history of surgery or radiation therapy in the pelvis; and name and address of physician or clinic submitting the specimen.

Since the cytology examination serves as a screening procedure, the laboratory report to the physician or clinic either indicates that the findings are negative or recommends further study—additional cytology specimens or biopsy, depending on the judgment of the pathologist—without specifying a provisional diagnosis. Because the initial cytology examination is made on a single vaginal pool specimen, slides containing abnormal but not definitely suspicious cells warrant, in addition to a second vagi-

nal pool specimen, a repeat examination with a specimen taken directly from the cervix.

A negative report is accompanied by a stamped postal card addressed to the patient, informing her that the results of her test are negative and urging her to repeat the examination in a year. The private or clinic physician signs the card and mails it to the patient.

Record Unit

The record unit of the laboratory keeps a record of all women for whom cytology specimens are examined, the results of this examination, and a record of tissue examinations up to the point of final diagnosis. Space is provided on the back of the record card for recording the cytology findings and the report of biopsy when this is recommended and completed.

The unit is staffed with a supervising clerk, 2 record clerks, and 1 coding clerk, who codes the recorded material for preparation of punch-cards to be used in the mechanical tabulation of data for analysis. The coding clerk also assists with routine recordkeeping when necessary.

The record unit keeps a tickler file of all patients for whom additional diagnostic study has been recommended. If the initial examination indicates a need for additional cytology specimens, the arrival of such specimens in the laboratory indicates that followup has been successful. If no specimens are received, further followup is carried out.

Followup

The physician is responsible for contacting private patients for whom the cytology report indicates the need for further study. Two weeks after the report is sent to the physician, the cytology laboratory makes a telephone inquiry to him concerning the patient's response. If a biopsy has been taken, the name of the pathologist who examined the specimen is noted, and his findings are recorded on the patient's card in the record unit. If a biopsy has not been taken, the laboratory contacts the physician's office periodically until the patient returns for further study and a report of the

results of examination is available. For both private and clinic patients, if cancer is found the case is closed as far as the cytology laboratory is concerned. Therapy becomes the responsibility of the private physician or the gynecology clinic.

The followup services of public health nurses are available to private physicians, although most physicians prefer to assume this responsibility themselves.

Clinic patients for whom further study has been recommended are followed up by the division of public health nursing of the Memphis and Shelby County Health Department. The cytology laboratory sends referral slips to the health department to be given to the general public health nurse who serves the area in which the patient lives. The nurse contacts the patient personally and makes clinic appointments for further examination.

The health department nurse responsible for supervising cytology referrals periodically checks with the record unit of the cytology laboratory to determine which patients are not responding to followup, and when necessary, she sees that additional visits are made by a general public health nurse. If repeated followup visits are unsuccessful, the supervising nurse makes a home visit in a final effort to persuade the patient to come in for further diagnostic study.

Clinics for Indigents

After the vaginal cytology study was organized, all adult female patients at the clinic for indigents in the Gailor Out-Patient Clinic of the City of Memphis Hospitals and the women who accompanied them to the clinic were informed that cytology examinations were available in the clinic newly established for that purpose. The large attendance, chiefly Negroes, and the response of the patient to the cytology service made this clinic a very productive source of material for study. Since the gynecology clinic is held in the same building as this cytology clinic for indigents, the latter has become the central clinic for indigent patients who come for repeat smears and for referral for further study.

In the clinic for indigents, vaginal pool speci-

mens are used exclusively. A trained nurse, who has had considerable experience in cancer clinics and several years' experience in taking specimens for a cytology laboratory, supervises the personnel who take the specimens.

In the interest of economy and efficiency, non-professional personnel take the specimens. They are supervised directly by the nurse in charge until she is satisfied that they are capable of working under general supervision. These employees also clean and sterilize vaginal pipettes and see that the kits furnished to physicians are equipped with slides, pipettes, and record forms.

These personnel were recruited through local employment sources from a group of intelligent but untrained young women. They were given some background information on genital anatomy and the symptoms of uterine cancer and instruction in the method of obtaining information for the record form, handling of patients, and the technique of obtaining a vaginal smear.

Two senior members of the resident staff of the division of obstetrics and gynecology are responsible for the clinical study of indigent patients with suspicious and positive cytological findings. All patients in this category are seen by these two physicians and are kept under their observation until tissue studies have been completed and a final diagnosis has been established. Patients who have cancer are hospitalized for treatment by the staff of the division. All tissue examinations of these patients are made in the division of pathology and bacteriology of the University of Tennessee. For uniformity of tissue interpretation in connection with the study aspects of the project, other pathologists of the area who examine biopsies from patients found to have suspicious cytology as a result of the project have cooperated by allowing these biopsies to be reviewed.

As the technicians taking specimens became sufficiently experienced, cytology clinics were opened in two other locations in the city where facilities for indigent patients are available. These are largely prenatal and well-baby clinics, and most of the patients are Negroes. The hope was that the publicity given the program would attract well women to the clinics, as well as women attending the other clinics operated in these facilities, but the response has been dis-

appointing. The cytology examinations are largely made on the regular clinic patients and on the relatives and friends who accompany them to the clinic.

Other Cytology Clinics

Parent-teacher organizations were informed about the project through publicity in the newspapers, over the radio, and through talks given at their regular meetings. Offers were made to open clinics in school buildings at hours which would be convenient for the women interested. A number of clinics were opened on this basis and attendance has been excellent.

In these clinics, each patient is asked for the name of her family physician, and the report of cytology findings is sent to him. If the patient has no physician, she is referred to the Memphis and Shelby County Medical Society for a list of recommended physicians. The results of the examinations are reported to the physician she chooses; no report is ever made directly to the patient.

Industrial organizations are another source of cytology specimens from well women. The management of a number of industries was informed of the nature and purposes of the project, and an offer was made to conduct cytology clinics for female employees. The response to this offer has been gratifying, and many industrial organizations in the study area have had the benefit of this service.

The usual plan for industrial organizations is to have two clinic sessions about 2 weeks apart. At the second session, patients whose examinations were unsatisfactory are reexamined, and women who were menstruating when the first clinic was held have an opportunity to take advantage of the service. Reports are sent to the family physician or to the plant physician, never to the patient.

Publicity

The mechanics of the cancer case-finding project makes public acceptance and cooperation crucial to its success. The project was initiated with a minimum of general publicity by newspapers and radio, for, with no previous experience in cancer case finding to draw upon,

there was no way of anticipating what the public's response would be. A widespread general response by the 165,000 women in the area who were eligible for the examination would swamp the available facilities. Therefore, it was necessary to work for an even flow of patients on a long-term, continuing basis. Also, to test the flow, processing, and reporting of specimens and reports, a "shakedown" period was considered necessary.

It soon became evident that the public was not overly conscious of cancer as a personal problem, and that more aggressive educational measures were needed. Yet it was necessary that publicity should not antagonize practicing physicians since their cooperation is a necessary part of the project.

The chairman of the policy committee is responsible for the supervision and direction of publicity. Facilities of the university are used to carry on the publicity, and regular announcements and descriptions of the project in local newspapers and on the radio are supplemented by donated space in store windows, billboards, advertising on buses, and pamphlets. Soon after the project began, an exhibit was presented at the local fair. Opportunities are sought to discuss the project before women's organizations and parent-teacher and church groups.

In the beginning, the publicity staff consisted of one full-time person, who devoted most of her time to working with Negro groups. Negro women are less inclined than white women to obtain the cytology examination voluntarily, although they are quite willing to have the examination when they are attending a clinic for another purpose. Added to the staff a few months later was a second person, who had gained considerable experience in public relations in the health field as a result of working with voluntary organizations.

Any apprehension about the public's over-consciousness of cancer has been completely dispelled. Enlightenment and motivation have become the leitmotifs of the publicity program in the effort to reach women individually through every possible medium, until they accept the fact that they can have cervical cancer, and that the cytology examination is a means of detecting this cancer in a curable stage.

Discussion

Progress of the study of vaginal cytology as a means of finding cases of uterine cancer has been very satisfactory. Only occasionally have the laboratory facilities been taxed to capacity. However, it is doubtful whether the laboratory as presently staffed could maintain the pace required by the original estimate of a maximum of 400 smears a day. Each primary screener can process 25 to 30 slides daily, a laboratory total of about 300, but personnel turnover, need to recruit and train new technicians, illness, and vacations make this potential difficult to meet. Nevertheless, the cytology laboratory has been able to provide the service demanded of it.

A preliminary report on the results of the study has been published elsewhere (2). It is sufficient to say that, in general, in the first 30,000 women examined, 90 percent of the smears have been negative; 6 percent have been unsatisfactory and a repeat examination has been requested; and 4 percent have been recommended for further study. Of these 4 percent, a little less than half have been recommended for biopsy after initial or repeat cytology study. Epithelial changes warranting a diagnosis of carcinoma in situ or invasive carcinoma of the cervix have been found in about half of the biopsy specimens.

Since vaginal smears are used exclusively for initial screening, records of cases of cervical cancer in the Memphis hospitals are checked against the records of the cytology clinic to determine whether these cases were missed by cytology examination. A few such cases have been observed. As a further check, the morbidity survey conducted prior to the beginning of the project is to be repeated (3) and known cases of cervical cancer will be checked against the cytology file to identify additional missed cases.

In a few instances, skeptics have put the cytology program to the test by submitting specimens from known or clinically obvious cases. There are no known instances in which the cytology examination has failed under these circumstances.

As stated earlier, repeat smears from the cervix as well as from the vaginal pool are requested when the original pool specimen cannot be classified as negative. The smear from the

cervix is examined by the technician trained in the examination of cervical specimens, and the new vaginal pool smear is studied by another technician. Each technician makes a report to the chief technician, who studies both report and slides and makes a final evaluation for the review of the pathologist in charge of the laboratory. In this project, cytology is used for screening; it is not competing with the tissue study for relative accuracy in final diagnosis.

Pelvic examinations are not an essential feature of the project. Private physicians use their own discretion in this matter. Indigent patients are not given pelvic examinations but are queried as to symptoms suggestive of cancer. If they have any questionable complaint, they are urged to go to the gynecology clinic without waiting for the report of the cytology findings. If smears contain unexplained microscopic blood, the patient is referred to the gynecology clinic for examination, regardless of the cytological evidence.

Because of staffing and other requirements, it is not feasible at this time to determine minimum costs per examination in this study, but we feel that the cost of cytology examination is not prohibitive when it is compared with the cost of other laboratory procedures. Cost estimates of cytology examination in other studies have ranged from 90 cents (4) to \$3.00 per smear (5), but it is difficult to determine what fixed costs, such as rent, are included in these figures.

Final judgment of the value of vaginal cytology will depend on the following considerations:

1. Can the periodic use of such a simple procedure as vaginal cytology in a population of women result in the diagnosis of cervical cancer sufficiently early so that it will become predominantly a curable disease?

2. Can the interval between examinations be safely extended to more than a year?

3. Will the public accept the cost of finding cancer in a curable stage by this method as a

substitute for prolonged treatment that is often only palliative and all too frequently hopeless?

Summary

A 3-year cytology screening program for cervical cancer in a general female population was organized in Memphis and Shelby County, Tenn., in 1951 and was put into operation in 1952.

The goals of the study are:

1. To determine whether periodic vaginal exfoliative cytology as a screening procedure can be used to diagnose cancer in the preinvasive stage.

2. To accumulate data for determining age-specific incidence and prevalence rates for both preinvasive and invasive cervical cancer.

3. To estimate the frequency with which vaginal cytology needs to be applied to be effective as a case-finding procedure.

4. To determine whether, through this case-finding procedure, cervical cancer can become largely a curable disease.

National Marriage and Divorce Statistics

—Progress Report, 1945–1955—

By HUGH CARTER, Ph.D.

WITH the increased emphasis on the family, as well as the individual, as a basic unit around which to plan public health activities, the need for statistics on family formation and family dissolution is generally recognized. The consequent increase in the demand for statistics on marriages and divorces has stimulated the development of registration systems, particularly within the last decade.

In general, State departments of health collect, process, and publish the vital statistics of individual States. Location of the State files or indexes of marriages and divorces in the vital statistics offices places the job of handling these records in the hands of persons already skilled in the management of vital records and saves the added overhead costs that would be incurred by establishing separate offices.

Increase in States With Central Files

The number of areas that maintain central files of marriage and divorce records has steadily increased. This is important since areas that do not maintain such files are not in a position to provide comprehensive statistics. In 1945, 34 areas maintained central files of

marriage records. By the end of 1954, 40 areas—36 States, 3 Territories, and 1 independent city—maintained central files (fig. 1). Divorce records were centrally filed in 23 areas in 1945. At the end of 1954, these records were centrally filed in 34 areas—30 States, 3 Territories, and 1 independent registration area (fig. 2).

In areas with no central files, it is possible to obtain certain data, but these are limited in scope and often incomplete in coverage.

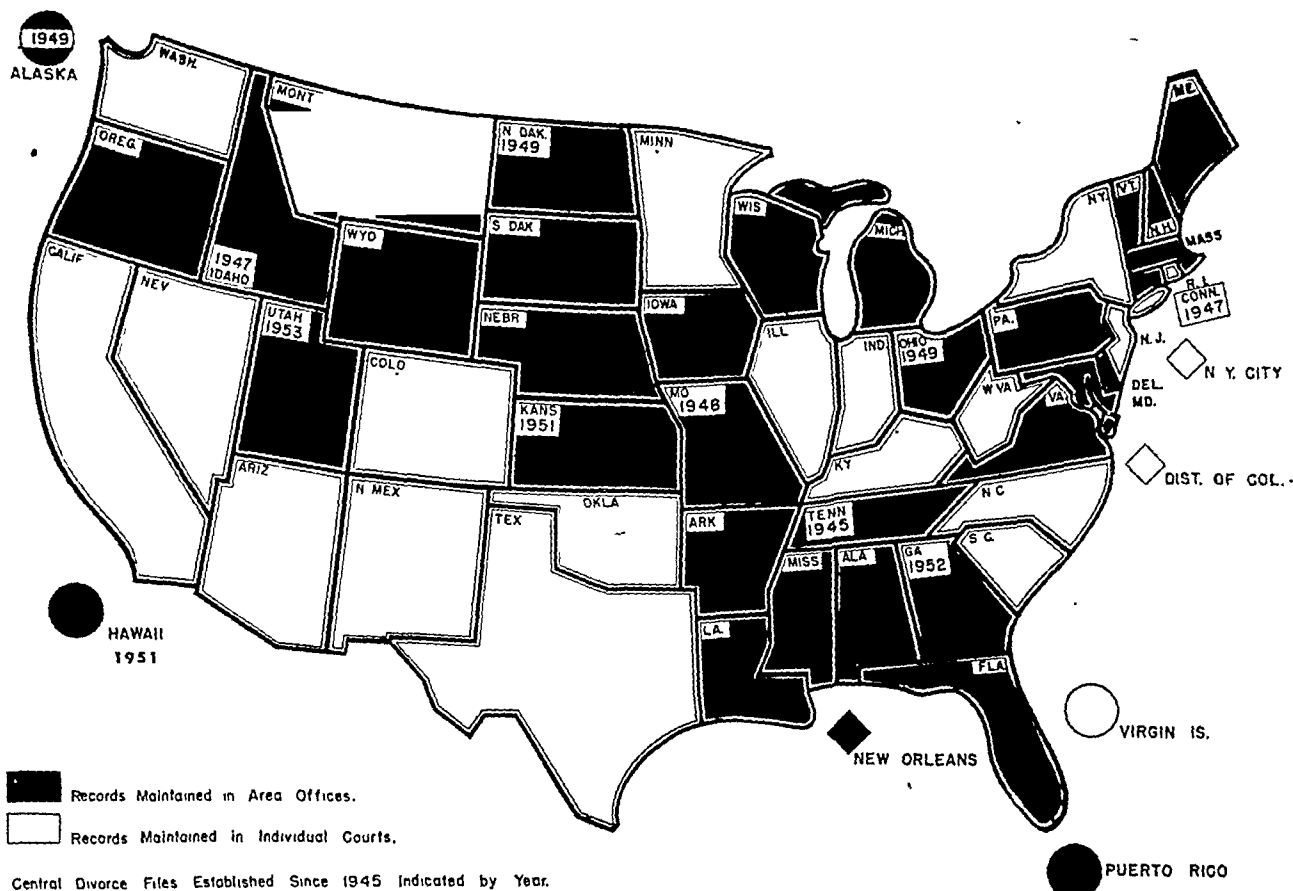

Standardizing Report Forms

Since 1945, great progress has been made toward standardizing the items of information to be obtained on marriage and divorce report forms. In 1954, the standard record of marriage and the standard record of divorce or annulment prepared by the Public Health Service were formally endorsed by the Public Health Conference on Records and Statistics, a cooperative organization made up of official representatives of the vital registration and public health statistical activities of each State, Territory, and independent registration area. A long period of discussion had preceded this action by conference members (1). The conference also recommended a list of optional items for inclusion on the State report forms to provide data for more intensive study of marriages and divorces.

Although some users of marriage and divorce

Dr. Carter is chief of the Marriage and Divorce Statistics Section, National Office of Vital Statistics, Public Health Service.

Figure 1. Forty areas maintaining centralized marriage records, 1954.

statistics will regret the omission of certain items from the standard record forms, the fact that such forms exist will mean improvement in the comparability and comprehensiveness of the national statistics that become available. The information requested on these forms and the optional items recommended by the working group are listed on pages 350 and 351.

Procedure manuals for use with the standard report forms are being developed by the National Office of Vital Statistics and the State registrars. These manuals will cover definitions of terms; suggested coding, punching, and tabulating instructions; and related matters.

Improvement in Available Statistical Data

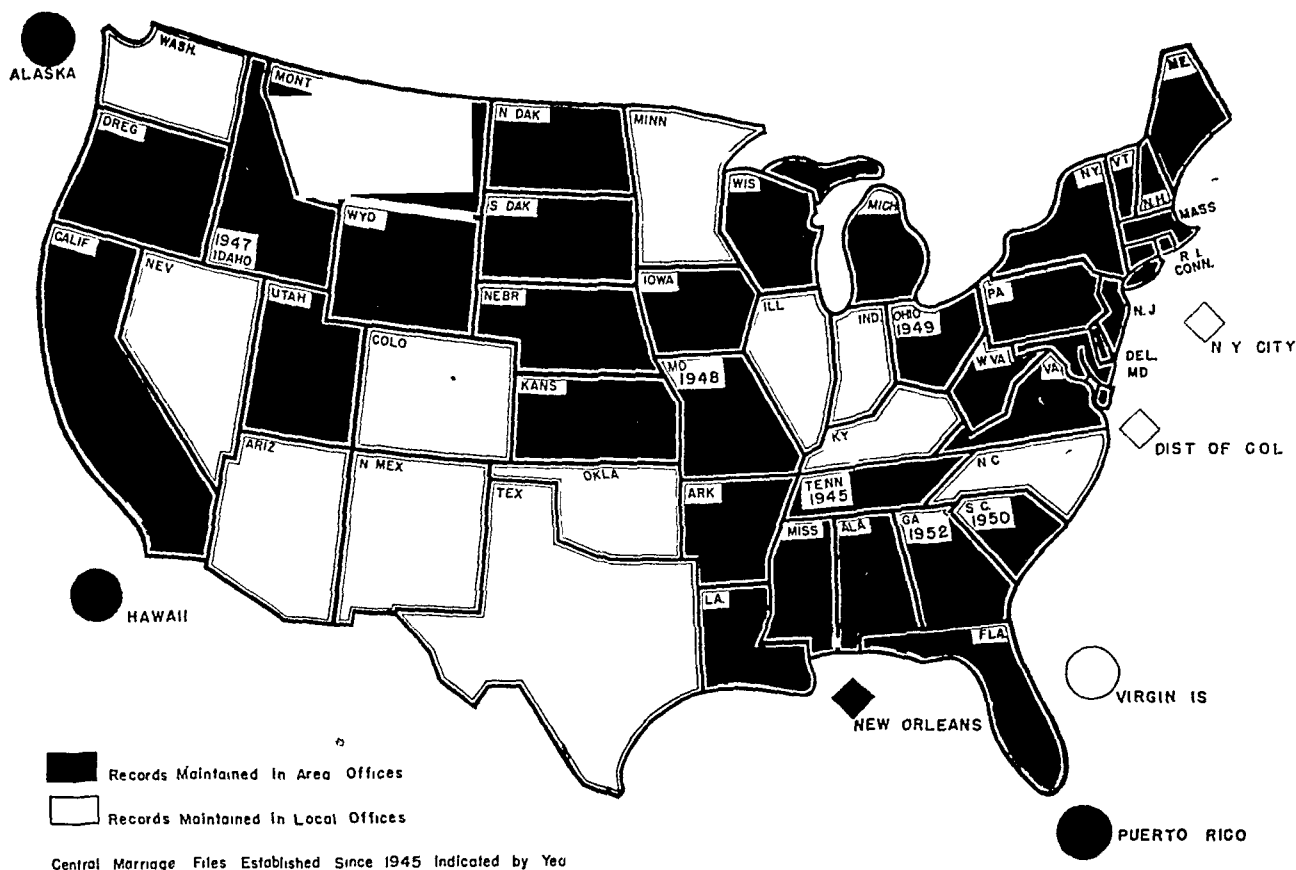

Since 1945, the accuracy of annual statistics of marriages and divorces for the United States has increased. The amount of necessary estimating for missing data from non-reporting areas has been reduced since more comprehensive reports are now received from the States.

Statistics on certain characteristics of persons recently married or divorced are published annually. Reports have been issued for selected areas since 1948 (2-10), and the number of areas providing such statistics has increased. Reports for 1953 have been received from 42 areas, including a few areas which do not have central files.

The data are tabulated according to table outlines distributed annually by the National Office of Vital Statistics. Under this program the cost of obtaining the data is minimal to the Federal Government. However, except for obvious errors and inconsistencies, it is impossible to ascertain the accuracy of the tabulations received from the States. Quality controls are the responsibility of each reporting State.

Monthly statistics of marriages or marriage licenses on a provisional basis have been published since 1944 (11-13). Special tabulations of marriage licenses for cities of over 100,000 population cover data from 1939 (13-16). Monthly statistics on divorces for reporting

Figure 2. Thirty-four areas maintaining centralized divorce records, 1954.

areas began with 1949 data. At that time regular reports were received from 16 areas (12). By 1954 the number of areas reporting divorces each month totaled 30 (13).

National statistics on the social characteristics of persons at the time of marriage are also being compiled on the basis of national sample surveys conducted in cooperation with the Bureau of the Census. The first of these surveys was carried out in 1953 (17) and the second, in 1954. These sample surveys have provided a valuable supplement to the presently incomplete data obtained from registration records. Additional reports will provide data on economic and social characteristics of recently married persons.

Plans for the Future

The Working Group on Marriage and Divorce of the Public Health Conference on Records and Statistics has recommended certain steps to improve national marriage and divorce

statistics. These recommendations have been given a vote of approval by the great majority of the members of the conference and are now being implemented as follows:

A registration area for marriage statistics is to be established, effective January 1, 1956. One year later a registration area for divorce statistics will be established. The criteria for admitting a State or an independent registration area to the marriage registration area, and later, to the divorce registration area, have been agreed upon. These include—

1. Central record files for marriages and divorces containing items on the standard record of marriage and standard record of divorce or annulment forms, in the State office.
2. Adoption of report forms of marriage and divorce containing the items on the standard record of marriage and standard record of divorce or annulment forms.
3. Regular reports to the State office by all local areas.
4. Agreement between State office and the

Information Requested on Standard Record of Marriage

Items on Form:

County

State file No.

Application for marriage license:

For both bride and groom—

Name (first, middle, last)

Date of birth (month, day, year)

Usual residence (State, county, city, or town)

Place of birth (State or foreign country)

Previous marital status

Number of previous marriages

Color or race

Usual occupation

Kind of business or industry

Date and signatures of applicants

Certification:

Date of marriage (month, day, year)

Place of marriage (county, State)

Date of recording

Signature and title of official making return to State health department

Optional Additional Items Recommended by the Working Group on Marriage and Divorce:

In States receiving original records of marriage, the word "Certificate" may be substituted for "Record."

In addition to "State file No.," provision may be made for "Local file No."

In item for "Usual residence," provision may be made for "Street address or RFD No."

The following items may be added:

Names of parents

Name or signature, title, and denomination of officiant

Religious preference or denomination of bride and groom

Possible additional items:

The item "Highest grade of school completed" has merit as an optional item for States that may be interested in the subject, although it was not discussed at the last meeting of the working group.

National Office of Vital Statistics on joint testing of reporting for completeness and accuracy.

The key criterion relates to tests of completeness and accuracy. Agreement is to be reached between the National Office of Vital Statistics and the individual States regarding the tests to be carried out in each State. These tests will aid in locating any imperfections in the reporting system of a given State so that remedial steps may be taken. In the preparation of a working document on tests of completeness and accuracy of marriage reporting, it became evident that the index to State files of marriage records was of crucial importance; consequently, a detailed study of such State indexes is being made. In the fall of 1955, it is planned to provide the Working Group on Marriage and Divorce with data on all States maintaining central files of marriage records and to ask the advice of the working group regarding the States to be admitted to the marriage registration area in January 1956.

A marriage registration test (MRT) in connection with the 1960 census has been proposed by several State registrars. This would parallel the birth registration test (BRT) in 1940 and 1950. This possible project will be explored with officials of the Bureau of the Census. A divorce registration test in 1960 has been suggested.

Further exploration will be made of sample surveys in obtaining useful marriage and divorce data. The results obtained so far are distinctly encouraging.

The needs of the consumers of marriage and divorce statistics will be studied by subcommittees of the United States National Committee on Vital and Health Statistics appointed by the Surgeon General of the Public Health Service. A subcommittee on utilization of marriage statistics is bringing together persons with varied interests to determine the types of information most useful to major consumer groups. It may propose a consumer survey. A similar committee on divorce statistics will be established at a later date. The reports of these two committees will provide a basis for possible modification of the program of marriage and divorce statistics to meet the needs of the consumers.

Information Requested on Standard Record of Divorce or Annulment

Items on Form:

County

State file No.

Local file No.

For husband—

Name, (first, middle, last)

For wife—

Maiden name (first, middle, last)

For both husband and wife:

Date of birth (month, day, year)

Usual residence (city, county, State)

Place of birth (State or foreign country)

Number of this marriage

Race or color

Usual occupation

Kind of business or industry

Place of this marriage

Date of marriage (month, day, year)

Number of children under 18

Plaintiff

Decree granted to

Legal grounds for decree

Optional Additional Items Recommended by the Working Group on Marriage and Divorce:

In States that grant other than absolute divorces, title may include word "Absolute."

In item "Usual residence," provision may be made for "Street address or RFD No."

To item "Number of children under 18" may be added "Number of children born alive this marriage."

To item "Legal grounds for decree" may be added "Number of children to custody of—husband; wife; other (specify)".

To item "Number of this marriage" may be added "Last marriage ended by—death, divorce, annulment."

To item "Place of this marriage" may be added "Date of separation" and "Place of separation."

Possible additional items:

The item "Highest grade of school completed" has merit as an optional item for States that may be interested in the subject, although it was not discussed at the last meeting of the working group.

PHS Civil Defense Training

The Public Health Service has offered the first of a series of 2-week training courses for physicians and other professional health personnel who would be called to duty in the event of enemy action or other national emergency.

The training courses are a phase of the Service's recently announced emergency program to expand its Commissioned Reserve Corps by 5,000 officers before July 1, 1956.

The course started on March 14, 1955. A second 2-week course is scheduled for May 15. Additional courses will be scheduled later.

Each course covers two main categories: one, the tasks with which a health department staff is generally familiar but for which additional help is required, such as those created by extensive disruption of public facilities and mass displacement of civilians in consequence of enemy action or natural disaster; and, two, the unusual tasks for which new skills as well as additional help may be needed by a health department, such as chemical, biological, and radiological warfare defense, epidemic reporting, monitoring radioactivity, decontamination, and related action.

During the first week, trainees spend 3 days at the Federal Civil Defense Administration Staff College at Olney, Md., on the outskirts of Washington, D. C. There they receive briefing on the strategic aspects of civil defense. The remainder of the period is spent at Public Health Service headquarters in Washington.

Additional information may be obtained from: Chief, Training Branch, Division of Personnel, Public Health Service, Department of Health, Education, and Welfare, Washington 25, D. C.

Gamma globulin, administered to a group of orthopedically disabled children in a hospital school, failed to prevent or modify measles in a proportion of the cases.

Effect of Gamma Globulin on Measles

By OTTO L. BETTAG, M.D., FREDERICK PLOTKE, M.D.,
and HAROLD M. STERLING, M.D.

THE INCIDENCE of complications with or following measles has led to various attempts at modification or prevention (1, 2). At present, the use of gamma globulin is considered the most effective means of preventing measles (3, 4). Since it is important in some instances to prevent this illness and in others to modify it, much effort has been directed recently toward establishing an optimum dosage (5, 6).

Current recommendations call for the administration of gamma globulin by the intramuscular route in a dosage of approximately 0.02 cc. per pound of body weight for modification and of 0.1 cc. per pound of body weight for prevention of measles (7-9). At least one worker has presented evidence that 0.02 cc. per pound of body weight is excessive since this "modifying" dosage frequently appears to prevent the disease completely (10).

The effectiveness of gamma globulin in preventing or modifying the course of measles was studied during an epidemic in the spring of 1954 at the Illinois Children's Hospital School, Chicago.

Dr. Bettag is director of the Illinois Department of Public Welfare, and Dr. Plotke is chief of the department's public health service. Dr. Sterling is medical director of the Illinois Children's Hospital School, Chicago.

The study included 92 permanent resident children at this institution. At the time of this report, the shortest period of residency in this hospital school was 2 and the longest 8 years.

The diagnostic categories included 35 children with cerebral palsy, 26 children with residual paralysis following poliomyelitis, 5 children with paraplegia following trauma, 2 children with paraplegia following transverse myelitis, 3 with paraplegia due to spina bifida, 5 with muscular dystrophy, and 16 with other disorders. The children in general represented the more severe forms of these conditions. Approximately one-third of the students are almost or totally helpless. In this latter group illness of any kind or complications thereof would be serious.

The review of the status of the children at the time of this study showed that of the 92 children, 16 had no history of exanthemata; 66 had a definite history, and 10 had a questionable history of measles (table 1).

The age range for the group was 5 to 20 years. The average age was 12 years; 82 were white, and 10 were Negroes; 52 were males and 40 females. The patients were observed under the condition of this study from March 1, 1954, to May 15, 1954.

For the study the children were divided into three groups:

Group 1 comprised 58 children in good physical condition who had a positive history of

Table 1. Immunity status of 92 children according to diagnosis

Diagnosis	Number of patients	History of previous measles	Questionable history of previous measles
Brain injury (cerebral palsy)-----	35	25	2
Postpoliomyelitis-----	26	23	0
Paraplegia-----	10	8	2
Muscular dystrophy-----	5	3	2
Other-----	16	7	4
Total-----	92	66	10

measles. These children were considered immune, and gamma globulin was not administered to them (11).

Group 2 consisted of 24 children in good physical condition who by history were considered susceptible. "Modifying" doses of gamma globulin were given to this group (12).

Group 3 included 10 children for whom measles, or its complications, was considered dangerous. This group was protected by the administration of "preventive" doses of gamma globulin, irrespective of a previous history of measles.

Group 3 consisted of:

Two students with previous history of measles, both manifesting severe respiratory difficulties following paralytic poliomyelitis.

Two students with indefinite history of measles; both had progressive central nervous system degenerative disease.

Six students with no history of measles—3 severe dystonic athetoid cerebral palsy cases, 2 muscular dystrophy cases, and 1 spastic paraplegia case with primary tuberculous infection.

The first case of measles in this epidemic developed March 5, 1954, in a child who was isolated in his room from the onset of the symptoms (except for part of one day) 3 days prior to the appearance of a rash. It was later learned that during a visit with relatives he was in contact with a child who subsequently developed measles. Immediately after the rash appeared in this first case, the child's entire residential floor was quarantined in an attempt to prevent the spread of the disease. Gamma globulin was administered to all those for whom it was indi-

cated on the fourth day of probable exposure.

During the following week several new measles cases appeared, but none occurred on the residential floor originally quarantined. As soon as the new cases were diagnosed, the 24 students in group 2 presumed susceptible because of no known previous attacks of measles were moved to a single residential floor. The group 1 students with natural immunity and the group 3 children with immunity passively conferred by gamma globulin continued as usual their activities of school, treatment, and home visits. For those quarantined, schooling and the various types of treatment were carried on in their quarters.

Six of the ten students in group 3 subsequently developed measles. One had an onset 11 days, two 12 days, one 17, one 18, and one 38 days after gamma globulin administration. Four children had mild and 2 had moderate cases. There were no significant sequelae to the infection. Thus, of the 10 persons for whom measles was presumed to be dangerous, 6 contracted the disease in spite of administration of the accepted "protective" dose.

The 2 children afflicted with moderate cases of measles also developed German measles 30 and 45 days, respectively, after the onset of their measles. Two others who did not have measles developed German measles approxi-

Table 2. The effect of preventive doses of gamma globulin according to disease category

mately 6 weeks after gamma globulin administration. One of these students, with progressive central nervous system degeneration (Pelizaeus-Merzbacher syndrome), appeared to deteriorate rapidly following relatively mild German measles.

A breakdown of patients developing measles after a "protective" dose of gamma globulin given at least 11 days prior to onset of symptoms is shown in table 2. The gamma globulin failures were distributed among a wide range of degenerative diseases.

Of the 24 students who received "modifying" doses of gamma globulin, 19 developed measles, and in 8 of these German measles developed subsequently. Four of the 19 had severe cases of measles and 4 others had complications of some sort.

Of the 58 students with positive histories of measles, 20 students developed measles, 4 German measles, and 3 had both. Three had some type of complications.

Summary and Conclusions

An epidemic of measles followed by an epidemic of German measles occurred in a residence school for 92 orthopedically disabled children, 16 having no previous history of exanthemata. The possibility of progression of basic conditions or of seriousness of sequelae prompted an attempt to prevent the disease in 10 pupils by the administration of 0.1 cc. gamma globulin per pound of body weight intramuscularly on the fourth day after exposure; 24 others received 0.02 cc. per pound of body weight to modify the illness; 58 students, who had positive histories of measles, received no gamma globulin and, therefore, were not quarantined.

Six children developed measles at least 11 days after receiving a "preventive" dose of gamma globulin. Of these, 4 had mild and 2 had moderate measles, but none had complications from this disease. One child suffered rapid progression of the basic condition following a subsequent attack of German measles.

A previous history of measles was of no value

in deciding who should receive gamma globulin, since 20 students with such histories developed measles, 4 German measles, and 3 both. Three had complications of some type.

Gamma globulin in the dosage currently recommended for prevention of measles failed to protect 6 out of 10 children to whom it was administered. Gamma globulin in "modifying" dosage apparently failed to modify the disease in 4 out of 19 students to whom this dosage was administered. There was no evidence that gamma globulin prevented or modified German measles.

Sources of Nurse Supply New Hospitals

By EUGENE LEVINE, M.P.A., MAURICE E. ODOROFF, M.A., MARGARET G. ARNSTEIN, R.N., M.P.H.,
and JOHN W. CRONIN, M.D.

THE OPENING of new hospitals in communities which formerly had none is attracting many nurses back to their profession. In 388 small communities that have built new hospitals since 1946 under the Hospital Survey and Construction Program, 2 of every 5 professional nurses employed on the staffs have come

back to work from "retirement." This is one of the findings uncovered in a survey of nurses employed in these hospitals.

The survey was undertaken because the existing shortage of nurses raised questions about the sources of nurse supply for new hospitals. There were some indications that nurses were attracted back to their profession because hospitals were built where none existed before.

Two years ago in Texas, the hospital survey and construction division of the Texas State Department of Health found that 1 of 5 professional nurses employed in Hill-Burton hospitals in the State had been inactive before their employment (1). This finding raised the question of what was happening on a nationwide

Mr. Levine is statistical analyst in the Division of Nursing Resources, Public Health Service. and Miss Arnstein is chief of the division. Mr. Odoroff is chief of the Evaluation and Reports Branch in the Service's Division of Hospital Facilities. and Dr. Cronin is chief of the division.

basis. The Public Health Service, through the Division of Nursing Resources and the Division of Hospital Facilities, designed a study to answer the following questions:

Are the new hospitals recruiting many members of their nursing staffs out of retirement?

Why do nurses take jobs in these hospitals?

How do nurses find out about the vacancies?

How well staffed are the nursing services?

How the PHS Study Was Conducted

Questionnaires were sent in May 1954 to 516 hospitals—388 new Hill-Burton hospitals and 128 hospitals established before the Hill-Burton program began. (The Hospital Survey and Construction Act was passed in 1946, Public Law 725, 79th Cong., 2d Sess.; and the first hospital was opened on October 15, 1948.) The latter hospitals, similar in location, size, and type to the Hill-Burton group, served as a control group and formed a basis for evaluating findings from the new hospitals.

The individual nurses filled out the questionnaires, and the hospitals provided data on bed capacity, patient census, staffing, and vacancies. One or more forms were received from 403 hospitals in 36 States.

Returns by type of hospital were as follows:

	<i>All hospitals</i>	<i>New</i>	<i>Older</i>
Number of hospitals where nurses received forms---	516	388	128
Number of hospitals returning 1 or more forms.	403	322	81
Percentage returns-----	78. 1	83. 0	63. 3

A total of 2,311 professional nurses in the new hospitals and 634 in the older group participated in this study. These participants represent two-thirds of the nurse staff of the new group and three-fifths of the nurse staff of the older group. The results of this study are considered reliable because of the large proportion of hospitals and nurses who responded.

Staffing Patterns

Three characteristics distinguish the 403 hospitals that participated in the survey:

Staffing the New Hospital

This recent study of recruitment of 2,311 professional nurses in new Hill-Burton rural hospitals and a control group of 634 nurses in 81 hospitals built before the Hospital Survey and Construction Program began in 1948 reveals the following facts: ▶Two out of every five nurses employed in rural hospitals (old and new) were previously housewives and thus retired from the nursing profession. New rural hospitals, by creating employment opportunities where none existed before, are attracting back to work many nurses who probably would have remained permanently inactive professionally.

▶The new Hill-Burton hospitals have fewer professional nurses per patient than the average hospital in the United States. However, they have so many more nonprofessional nurses that the total number of nurses per patient is higher.

▶Fifteen percent of the professional nurse positions in the new hospitals are vacant. There is some evidence in the survey that these hospitals have a fairly high turnover rate—although probably no higher than other hospitals.

▶Many nurses who previously were working in hospitals in other localities came to work in new hospitals because they could return to their home towns to live. Most inactive nurses returned to work in order to help relieve the nursing shortage or to assist with the financial upkeep of their families.

▶The best way to recruit new nursing personnel is by personal contact. Hospitals can help solve staffing problems by keeping good relations with their own employees and with the public.

They are small—97 percent of both these new and older hospitals have less than 100 beds (table 1) compared with 66 percent in the country as a whole.

They are the only hospital facilities serving areas where they are located.

They are located in towns serving semi-rural and rural areas—the majority in towns of less than 5,000 people (table 1).

Because of these characteristics, the problems of recruiting nurses in these hospitals are different from those in large cities. Surveys of nursing needs and resources in various States during the last few years have indicated that

| *Many physicians have served in Samoa, but few have written about the health problems of these enchanting islands.*

Notes on Public Health in American Samoa

By EDWARD KUPKA, M.D., M.P.H.

AMERICAN SAMOA is the only United States possession south of the Equator. Just within the southern limit of the Torrid Zone and south of Hawaii, it comprises the smaller eastern end of an archipelago of islands, the western end being a New Zealand trust territory, and formerly a German possession.

American Samoa is made up of seven islands, chiefly Tutuila and the three small islands known as the Manua group. The inhabitants are Polynesians, of the same race and with almost the same language as Tahitians, the Tongans, and the Hawaiians. In number 18,000, these people live on the narrow rims of the islands, between the volcanic mountains that cover most of the area and the beaches.

The island economy is agricultural. The Samoans cultivate taro, breadfruit, and coconut. They catch shellfish and fish and raise pigs and chickens. Several or many families

form a village, presided over by village elders and an elected chief. The primary loyalty of each Samoan is to his village, which gives him complete security in exchange for his work and faithfulness.

The Samoans are Christians, although their religion incorporates some of the rudiments of their earlier beliefs. Their manner of life has changed little since Margaret Mead wrote her famous "Coming of Age in Samoa" three decades ago.

Under Navy Administration at First

When the United States Government, at the request of the chiefs of eastern Samoa, and as part of a treaty arrangement with England and Germany, took over the sponsorship and the protection of the islands at the end of the 19th century, the task of administration was given to the Department of the Navy. A high-ranking naval officer was selected as Governor, assisted by a staff of Navy administrative and technical personnel.

A legal code, which combined basic American law with a respectful regard for Samoan custom, was adopted, and a strong legislative body composed of all the senior chiefs was established. Roads were built, utilities created, and homes, offices, workshops, and warehouses were erected.

The harbor at Pago Pago, considered one of the best in the world and made known to literature by Somerset Maugham's "Rain," became

Dr. Kupka is the coauthor of the article "Enforced Legal Isolation of Tuberculous Patients," which appeared in the April 1954 issue of Public Health Reports (p. 351). These notes are based on first-hand information obtained while he was on a 3-month assignment to American Samoa in 1952. At present, he is the regional public health administrator for Laos, United States Operations Mission to Cambodia, Laos, and Vietnam, and on leave from the bureau of tuberculosis control, California State Department of Health.

the site of a naval base. During World War II, Tutuila was a Marine base, and scores of thousands of Americans were temporary residents there.

In 1951, by Presidential decree, the Navy closed the base, and the Department of the Interior was given administrative responsibility for American Samoa and for the Trust Territory of the Pacific Islands.

Since then, the Governor of American Samoa and his administrative and technical employees have been civilians, and usually American citizens. Samoans themselves are assuming more and more of the governmental positions as they acquire the necessary training, particularly in the field of teaching.

The Public Health Structure

The Government departments are six: administration, justice, public works, Samoan affairs, education, and public health.

The Public Health Department is responsible for both preventive and curative activities.

The department's medical staff comprises a chief, a deputy (whose special functions are in the field of preventive medicine and the supervision of the district dispensaries), a surgeon, an internist, a pediatrician, and a tuberculosis specialist.

Staff members are usually Americans, although physicians educated in Europe have also been employed.

The nursing staff consists of a chief, the head of the nursing school, a public health nurse, and a tuberculosis head nurse. These positions are provided in the organization plan but are frequently vacant because of recruitment difficulties, so that doubling up of functions is common. (The same applies to the physician staff.) The duty period is 2 years.

There is a much larger cadre of Samoan physicians and nurses. The 12 Samoan physicians have the degree S.M.P., the abbreviation for Samoan medical practitioner. They are not considered fully trained physicians at graduation by our standards; their training was received either at the Suva Medical School in the Fiji Islands or at a similar institution which the Navy maintained for a time at Guam.

Promising young men from the various is-

lands of the South Pacific who speak some English are given a training which enables them to do simple medical practice. Some, by later serving for long periods under American physicians, become highly experienced and can be entrusted with major responsibilities.

Eight of the Samoan medical practitioners are at the Government of American Samoa Hospital, each in charge of a ward or clinic. The others serve in the four district dispensaries. During their early years they are rotated through the various services in order to give them broad experience.

The Samoan medical practitioners relieve the physicians of many of the routine duties: They take histories, perform and record physical examinations, and make progress notes. They write routine orders and keep the outpatient clinic records. They screen night calls and see to routine matters.

A Samoan medical practitioner is at the side of the physician most of the time, not only for his own training, but to give assistance and to act as translator since few of the patients speak English.

Including active graduates and present students, there are about 100 Samoan nurses who were all trained at the hospital and given the degree of S.N., which stands for Samoan nurse. The chief Samoan nurse was a member of the first graduating class almost 40 years ago.

Samoan nurses are carefully chosen Samoan women; they receive 4 years of training under Samoan and American nurses, somewhat comparable to the 3-year basic training in the United States, but with less academic and more practical training, rotating through all the services. Many marry and are lost as full-time nurses, but they remain a force for health education in the villages to which they return.

All physicians and nurses are government employees and enjoy high prestige. Nursing is about the only profession that a Samoan woman is permitted by her culture to enter. In the social scale, the Samoan physicians rank next to the chiefs and the pastors.

The Government of American Samoa Hospital is located on the west shore of Pago Pago Bay, on filled land, a scant half mile from the governmental offices and population center. It was built after World War II by uniting wooden

2-story military barracks in series, and putting the main service, administrative, and clinic functions into a new central concrete section.

The hospital can accommodate 250 patients. The largest number of occupied beds is for tuberculosis patients; next in order are those for pediatrics, surgery, medicine, and obstetric patients.

A small building separate from the hospital houses the leprosarium.

The Samoan nurses in residence live in remodeled barracks in front of the hospital, and the American employees live in cottages along the edge of the bay, a few hundred feet away.

The curve of foothills around the hospital grounds, heavily wooded, almost hides Utulei, one of the largest of the island's villages, where many of the Samoan employees live.

The district dispensaries were first established by the Navy and operated by pharmacist mates. They are located at outlying centers of population. Two are on the Manua Islands, 80 miles from Tutuila, and are connected by radio and by government steamer, which makes scheduled and emergency trips.

The larger of the dispensaries has a 10-bed hospital and the most experienced of all the Samoan medical practitioners.

Each dispensary is well supplied with drugs and first aid equipment, 1 or 2 beds for urgent care or deliveries, a minor surgery, and staffed by a Samoan medical practitioner and 2 or more district nurses. The dispensaries give first aid, treat minor illnesses, and perform normal deliveries. More serious cases and most major surgery are sent to the hospital.

With this staff and medical plant, the general and special medical and public health functions are conducted in a conscientious and thoroughgoing manner. The Samoan medical system ranks high among those of the Pacific Islands. The pioneering efforts of many Americans, Navy and civilian, contributed much, but the major factor in the success of the system was the intelligence and cooperation of the Samoans themselves.

No Malaria, No Syphilis

In approaching the special disease problems of the islands—all in the field of transmissible

diseases—one should first note that there have never been recorded any cases of malaria or syphilis although these diseases are common elsewhere in the South Pacific.

The absence of a suitable vector explains the freedom from malaria. Freedom from syphilis has been alleged to be due to the fact that most Samoans have had an episode of yaws early in life.

Yaws is a common problem but no longer a serious one because of the effectiveness of treatment in the early stages.

The Navy established yaws teams which went from village to village, treating everyone with lesions or suspected lesions of the skin. Arsenicals were used at first, and later penicillin. Severe lesions of active destructive yaws are rarely seen today.

Traveling teams are not now used, but dispensary nurses in their work in the villages find the yaws cases and send them to the hospital for treatment or treat them on the spot.

Intestinal parasitic infestation is almost universal after early childhood. Routine stool examinations were formerly made at the hospital, but since most of the patients were found to be positive for one or, more commonly, several parasites, this examination is now done only when especially indicated.

The Samoans tolerate their parasites well. *Ascaris* and *Trichuris* are the most common. *Ancylostoma* is of moderate frequency. Because they may play a secondary role along with malnutrition, in the serious pneumonias of early childhood, "deworming" clinics are held for children of all ages regularly at the beginning of each school semester.

The Government of American Samoa has been sending patients with leprosy to Makogai in the Fiji Islands where there is an excellent large leprosarium. The sufferers from Hansen's disease are thus sent 800 miles from home, and many, at least in the past, never return. This circumstance makes persons with the disease reluctant to seek treatment.

Although the Makogai institution is pleasantly located, and well run, with up-to-date treatment, and the Samoans carry on their own village life there, separated from the Fijis, the love of their own islands and villages at home is

strong, and they understandably do not want to go away.

About 40 American Samoans are at Makogai (pronounced *Makognai*). The reluctance of the others to seek treatment has been partially remedied by the building of a 10-bed leprosarium behind the Government of American Samoa Hospital, for isolation, observation, and initial treatment. The present plan is to enlarge the leprosarium or to build a small colony nearby for all of the leprosy patients on Tutuila. With modern drugs and ambulant treatment, a small unit may suffice.

Filariasis and Tuberculosis

The two chief transmissible diseases are filariasis, and that special plague of the South Sea Islanders, tuberculosis. Acute bacterial pneumonia is the chief cause of death among the Samoans.

Filariasis, which was of considerable importance among military men stationed in many of the South Sea Islands during World War II, is a common and serious disease, though fortunately its chief sequela, elephantiasis, is rapidly decreasing in prevalence. Elephantiasis results from repeated exposure over a long period of time.

The parasite causing filariasis is *Wuchereria bancrofti*. The vector is *Aedes polynesiensis* (until recently called *Aedes pseudoscutellaris*), which inhabits the bush only and has a very limited flight range, so that the disease is not contracted in the villages. Since, however, a staple food on the island is taro root, much of which is cultivated in the bush, the Samoans, particularly the men, are exposed.

A special filariasis clinic is held weekly at the hospital. Hetrazan is fairly effective against microfilaria, and courses of this therapy are given to patients and suspects. Surgery is sometimes necessary for the disfiguring end effects, especially for filarial hydrocele.

Control of the vector mosquitoes is difficult. Special attention to this problem is being given in Tahiti, where the disease is even more serious, by a research institute for tropical diseases under the leadership of Dr. John Kessel of the University of California at Los Angeles.

Tuberculosis is the second leading cause of

death and is the chief public health problem. Almost half the bed capacity of the hospital is used for the treatment of tuberculosis. An aggressive case-finding program was put into effect in the last 2 years, with routine chest films of all hospital admissions, a weekly chest clinic, and tuberculin testing of high school students and other groups.

As in many Pacific islands, tuberculosis became a veritable acute plague after its introduction in Samoa by Europeans more than a hundred years ago, with the coming of the first missionaries. The verbal traditions handed down from those days describe the severity of the epidemic.

Today, the Samoan seems to have traveled well along the road toward increased immunity. The acute forms of tuberculosis are now not often seen, except for tuberculous meningitis in young children. As in the continental United States, the usual forms found are the pulmonary exudative-fibrotic and fibro-caseo-cavitary varieties. Scrofula in children still occurs.

Minor collapse measures and antibiotic therapy were introduced by the Navy and intensified during the past 2 years. Thoracic surgery is a present lack, and the possibility of using a visiting thoracic surgeon should be further explored. Thoracoplasty and excisional surgery will help clear the beds now occupied by some who otherwise will not be able to be rid of their cavities and who therefore continue to be infectious.

The enthusiastic cooperation of the Samoan is of great value in the control of tuberculosis: He reports early for treatment of symptoms; he is cooperative and quite content to stay in the hospital until discharged.

In 1952 the death rate from tuberculosis among American Samoans was about 80 per 100,000. This figure is probably a minimum, for some, not many, undiagnosed tuberculosis deaths occur in the villages.

Young adults and young women especially are the most affected age and sex group. The current tuberculosis picture may be likened to that found in the United States 30 years ago. Although the resources of the hospital are being strained by the large number of cases of tuberculosis found in the last 2 years, the prospect of effective control in the near future is good.

cases of tuberculosis, their contacts, and also the tuberculosis suspects who have been referred to private physicians by the countywide survey and who have not as yet had decisions regarding the presence of active tuberculosis. The contact programs are scheduled, usually, to take place in counties in which countywide surveys were held the preceding year.

In addition to these two types of programs, X-ray surveys of special groups are carried on throughout the year. These are directed toward county homes and other institutions, to groups of food handlers, to industries, to colleges or other schools, and to small communities not covered by countywide surveys. In some instances the special program consists of 70-mm. film screening only, from which suspects are referred to private physicians for repeat X-rays. In other special groups, such as county homes and State and county institutions, suspects on the 70-mm. film are X-rayed again by the State health department units as is done in the countywide survey and the contact programs.

The 5 mobile units participating in these 3 programs are equipped to take both 70-mm. and 14" x 17" films. Three of the units are owned by the Iowa State Department of Health, and 2 are owned by the Iowa State Tuberculosis and Health Association.

The Countywide Survey

The countywide survey generally consists of a large-scale appeal to people to accept an X-ray of the chest. An attempt is made to get an X-ray schedule into every home in the county, and, in addition, many persons are X-rayed at their place of work. School children, beginning with the seventh grade, are also included in this program. Persons who are positive to the 70-mm. X-ray are urged to return at a specified time for a 14" x 17" plate. All persons with suspected "tuberculous pathology" are referred to their physicians for confirmation of the diagnosis.

During 1952, surveys were held in 19 counties with an estimated total eligible (15 years and over) population of 293,327. Chest X-rays were performed for 222,441 (75.8 percent) persons. Of this number, 220,409 (99.1 percent)

were not recalled for a 14" x 17" film, and 2,032 (0.9 percent) were recalled for further examination (table 1).

This unusually low percentage of persons recalled for a large film may be partially explained by the fact that persons with readings of suspected nontuberculous chest diseases, with the exception of neoplasm, were not recalled for 14" x 17" films.

It was not considered necessary to recall for a large film those persons suspected from the reading of the 70-mm. film of having cardiovascular abnormalities and other conditions such as thoracic cage anomaly, lung anomaly, and abnormal diaphragm. Instead the film interpretation was reported by letter to the person's physician, and the individual was notified to see him for a report of the X-ray findings.

Of the 2,032 persons recalled for a 14" x 17" film, 1,790 received that type of X-ray, approximately one-fourth (493) were considered essentially negative, and one-fourth (384) as having tuberculosis (see table 1). The remainder, approximately 50 percent, were described as having findings other than tubercu-

losis—findings such as pneumonitis, possible neoplasm, emphysema, and hilar node calcification. Two hundred forty-two persons had confirmatory films taken privately, or did not live in the area, or had moved away.

Of the 384 persons who were considered tuberculosis suspects on the 14" x 17" film, 131 are described as previously known to the health department or not reportable (primary complex). The remaining 253, or approximately 1 per 1,000 persons examined, were referred to the physicians for followup and confirmation of diagnosis of tuberculosis. Among the replies from physicians and among the morbidity reports submitted by physicians, which were matched against the results of the X-ray, were 28 cases of active or questionably active tuberculosis which can definitely be ascribed to the survey as the case-finding mechanism. This is approximately 1 case per 8,000 persons examined.

Toward the end of 1952, queries were mailed from the State health department to physicians who had failed to report on cases referred to them from countywide and contact programs. Queries were sent on 281 cases; 125 answers were received as follows:

Seventy-five stated that patients had reported, were under physicians' care, but did not confirm the diagnosis of tuberculosis.

Ten confirmed the diagnosis.

Forty replied that the patients had not reported to them.

One hundred and fifty-one did not reply. Second letters were not sent to these persons. It appears likely that more cases of tuberculosis existed than were reported on by the physicians.

The Contact Program

In preparation for a county contact program, records of reported cases or suspects in the county and all information regarding contacts of patients, including the results of previous X-ray readings, are sent by the State health department to the nurse who is to work in the county.

The nurse visits all physicians in the county and obtains their permission to call on cases, contacts, and suspects. She also asks the physician for the names of any persons on his patient

roster who may be suspected of having tuberculosis or for whom he feels an X-ray of the chest would be advisable. The X-ray in this program is a 14" x 17" film since it is considered more of a diagnostic procedure than a screening procedure.

Tuberculin testing of contacts and suspects before the survey is recommended, and the physician is supplied with sufficient tuberculin for this purpose. Some physicians prefer to have their patients receive the 14" x 17" X-ray without prior tuberculin testing.

The results of this program for 1952 are shown in table 2. A total of 2,234 persons received a large film. Of these, over half (53.3 percent) had positive readings; 714 were positive for nontuberculous pathology; and 477 were suspected of having tuberculosis. Most of these persons had previously been reported as having tuberculosis, and of those referred to physicians for diagnosis, 11 were reported as new active cases of tuberculosis.

Special Group Surveys

Special X-ray programs in 1952 consisted only of the 70-mm. X-raying or screening phase. The names of persons with positive results at screening were referred to private physicians with recommendations for a large film. Records of the results of followup of suspects are not available.

In some programs, such as those conducted in county homes or in mental institutions, all persons with positive 70-mm. X-rays were re-

called to have 14" x 17" films taken. In programs in which recall was included (county homes and the mental institutions), approximately 10 percent of those receiving 70-mm. X-rays were recalled to have the large films taken.

Two active cases of tuberculosis never previously known were discovered by this project. This is approximately 1 active case for each 1,500 70-mm. X-rays taken on persons in county homes and mental institutions. Undoubtedly, these 2 active cases are not the only ones discovered as a result of this survey since approximately only one-third of the 70-mm. films were subject to recall, two-thirds of the suspects had been referred to physicians on the basis of the 70-mm. X-ray, and no record of followup for these groups is available in the State health department.

Tuberculin testing of special groups has been developed and conducted as a special program in case finding. Entire school populations, usually limited to the seventh grade and over, have been tuberculin tested in some areas, and in other areas just selected grades have been tested. All those having positive reactions are X-rayed, and their associates are also examined for the presence of tuberculosis.

We see then that within the limits of reporting by physicians on the results of their follow-

up there were discovered through all these State programs at least 184 new cases of tuberculosis, of which 41 were active or questionably active. It is likely that some cases of tuberculosis diagnosed were not reported back by physicians, and among the 126 cases described as inactive, continued examination will show some to be active.

The 41 active cases may be considered the minimum accomplishment of the case-finding program. It is interesting that these 41 active cases are approximately 8 percent of all the cases of active tuberculosis reported in Iowa during 1952.

We may generalize that at least 8 percent of all the active tuberculosis discovered in the State of Iowa during 1952 was discovered as a result of these statewide case-finding efforts.

Another Approach

Analyzing the reasons for coming to diagnosis is another way to examine our case-finding program and, of course, is a different approach from the one previously described.

In this analysis we start with the cases diagnosed as having tuberculosis or with the cases admitted to a sanatorium. Then through a retrospective study we attempt to find out what were the reasons which led to the diagnosis of

Table 3. Reason for coming to diagnosis—patients admitted to Oakdale Sanatorium, Iowa, with active tuberculosis, 1952

Stage on admission	Symptoms		Contact investigation		X-ray survey		Hospital admission X-ray		X-ray by nurse		Followup of inactive tuberculosis		Other		Total	
	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent	Number	Percent
Minimal	3	30	3	30	1	10	0	0	2	20	1	10	0	0	10	100

Percent far advanced	77		33		23		33		0		17		80		65	
Mean age	46		26		41		55		28		46		44		44	

tuberculosis. In a way we are trying to discover motivation: that is, what is the underlying cause that gave rise to the chain of events that led to the person presenting himself to a physician or to an X-ray survey to find out if he had tuberculosis.

Data for the cases of tuberculosis admitted to the State sanatorium at Oakdale, Iowa, during the calendar year 1952 are presented in table 3. There were 176 of these cases: 10 were minimal; 48, moderately advanced; and 115, far advanced. We had already noted from the data released by the Public Health Service that the proportion of far advanced tuberculosis is higher for Iowa (52.7 percent) than for any State in the United States (1).

In our study we included factors which would help us to find out why such a large proportion of the new cases in Iowa are in the far advanced stage.

It will be noted that 74 percent of the cases admitted to Oakdale Sanatorium are described as having been discovered because of the person's own index of suspicion. This means that these people presented themselves to physicians for diagnosis because of symptoms which are ordinarily associated with tuberculosis. Contact investigation was the underlying reason for 7 percent, and a similar percentage came to diagnosis because of X-ray surveys.

It is perhaps worth noting that whereas analysis of the Oakdale figures shows that 7 percent of the admissions in 1952 were diagnosed because of X-ray surveys, our previous study showed that 28 cases of active tuberculosis were reported as being discovered in Iowa during 1952 because of the mass X-ray survey (approximately 8 percent of all the cases reported in Iowa). Thus, we note that both analyses tend to give the same result: Between 7 and 8 percent of all the active tuberculosis diagnosed in Iowa is diagnosed because of mass X-ray surveys.

It is also interesting that routine X-raying of all admissions to a general hospital produced 3 percent of the tuberculosis, examination of nurses produced 2 percent, and followup of inactive cases of tuberculosis produced 3 percent.

Of all the cases coming to diagnosis because of symptoms, 77 percent were in the far advanced stage. It is also of significance that

for other designated methods of case finding the proportion in the far advanced stage was never higher than one-third. This means that when we go out and aggressively look for tuberculosis among people who are not symptomatic and who are not going to their physician because of symptoms, two-thirds of the tuberculosis discovered is in a stage prior to far advanced.

We may also wish to consider the age of persons found by these various methods. It will be noted that, except for those found through hospital admission X-ray, the persons motivated by symptoms were the oldest, and those found through contact investigation and followup of student nurses were the youngest. Nevertheless, comparison with the rest of the United States shows that the tuberculosis patients reported in Iowa are not older than the average for the continental United States, according to the Public Health Service (1).

In the United States in 1952, more than 12 percent of the tuberculosis patients reported were of age 65 and over. In Iowa, less than 10 percent were in that age group. Other age groups show no great differences except that in Iowa a slightly smaller percentage of the tuberculosis patients reported was under 5 years of age than in the United States (1.0 versus 3.1).

Here, then, is a partial answer to our question as to why Iowa, with its low morbidity and mortality rate, has such a large proportion of its cases diagnosed in the far advanced stage. Three-quarters of all the cases of tuberculosis diagnosed in Iowa, as judged by the admissions to Oakdale Sanatorium, have come to diagnosis because of symptoms associated with tuberculosis. In other words, their tuberculosis has progressed to a stage where their symptoms are sufficient to arouse suspicion of tuberculosis or at least to motivate them to go to their physician to find out what ails them.

Indicators for the Future

What then can Iowa do about this large proportion of cases in the far advanced stage?

In what direction shall our case-finding program of the future be?

In view of the fact that 3 out of 4 patients come to diagnosis because of symptoms, shall we discontinue organized case finding and rely on

people to go to their physician when they are sick?

The answer to the last question is "No."

In Iowa, during 1952, 506 cases of active tuberculosis were reported; if the Oakdale distribution can be applied to these cases, we can say that 26 percent, or 132 cases of active tuberculosis, was found through organized case finding by health department effort. We can assume that most or all of these were benefited by early case finding and that, in addition, the community gained by taking out of circulation so many cases of infectious disease. Our problem is how to keep on removing from their environment this proportion of active cases, or a larger proportion, and to do it as early as possible.

Our case-finding programs of the future then would seem to be:

- ▶ Continued intelligent followup with periodic examination of all suspects and known inactive cases with special reference to cases referred to private physicians.

- ▶ Realistic followup and periodic examination of all contacts of active cases of tuberculosis.

- ▶ Expansion of routine X-raying on admission to hospitals and other institutions.

- ▶ Admission and periodic X-raying of inmates of mental sanatoriums, prisons, and other institutions for long-term care.

- ▶ Continued X-ray surveys of groups and areas of presumably high prevalence, such as the aged, transients, food handlers, overcrowded areas of our cities, and so forth.

- ▶ Preemployment X-raying and periodic examination of industrial groups and others who can have X-ray facilities made readily available.

- ▶ Continued tuberculin testing of students with X-ray of the positives and examination of contacts and associates.

Tuberculin testing of whole communities on an experimental basis with X-raying of all positive reactors would appear to be indicated.

Experience in a few areas would give us valuable information both from an administrative and epidemiological point of view regarding the merit of this method as a case-finding procedure.

Summary

Two studies were made to evaluate tuberculosis case-finding procedures in Iowa.

One study shows that during 1952 at least 184 cases of tuberculosis, 41 of them active or questionably active, were found by the statewide program of the State department of health; these were found chiefly through X-raying. This number is approximately 8 percent of the active tuberculosis reported in Iowa in that year.

Another study of the reason for coming to diagnosis shows that approximately 75 percent of all cases of tuberculosis diagnosed in 1952 came to diagnosis because of symptoms related to tuberculosis. X-raying of the public produced 7 percent; contact investigation, 7 percent; and the remainder were found through followup of inactive tuberculosis, X-raying of hospital admissions and staff, and so forth.

Some of the possible reasons for such a large proportion being diagnosed because of symptoms are discussed, and the case-finding program for the future is proposed.

ACKNOWLEDGMENT

Acknowledgment is made to Dr. W. M. Spear, medical director of the Iowa State Sanatorium at Oakdale, for his cooperation in making available for analysis the records of admissions during 1952.

REFERENCE

- (1) U. S. Public Health Service: Reported tuberculosis morbidity and other data, calendar year 1952. Washington, D. C., The Service, 1953, 17 pp. Not available for distribution.

A new medical statement, issued by the American Heart Association's Council on Rheumatic Fever and Congenital Heart Disease, gives current preventive measures. Prepared by the council's Committee on Prevention of Rheumatic Fever and Bacterial Endocarditis, the statement was first published in "Circulation," February 1955, and has had special distribution as part of the "Stop Rheumatic Fever" campaign.

Rheumatic Fever Prevention

A new statement on the prevention of rheumatic fever and bacterial endocarditis, issued in January by the American Heart Association, incorporates the important advances made in the field during the past 2 years.

The statement, a revision of the January 1953 report, presents techniques for treating and preventing streptococcal infections to forestall both initial rheumatic fever attacks and recurrences. It also recommends measures for preventing bacterial endocarditis, an occasional aftermath of rheumatic fever.

Among the new developments is the emphasis on eradication of streptococcal infections from the throat by full doses of penicillin. Recommended for the first time are intramuscular injections of long-acting benzathine penicillin G. In the long-term prevention of rheumatic fever recurrences, one tablet of penicillin a day has been found adequate.

With the issuance of the revised statement, the Public Health Service and the American

Heart Association are planning a cooperative campaign, starting this spring, to help communities establish rheumatic fever prevention programs, aimed at eventual eradication of this disease. A new film, booklet, and other education material have been prepared for distribution to the general public through local heart associations and health departments in the "Stop Rheumatic Fever" campaign.

Although the number of rheumatic fever deaths has been declining, some 1,500 children and young persons under 25 years of age and more than 19,000 others above age 25 died of rheumatic fever and rheumatic heart disease in 1953. Many thousands of new cases of rheumatic fever occur each year, and there are many more thousands of "old" cases.

Following is the revised statement entitled "Prevention of Rheumatic Fever and Bacterial Endocarditis Through Control of Streptococcal Infections."

Treatment of Streptococcal Infections in the General Population

In the general population about 3 percent of untreated streptococcal infections are followed by rheumatic fever. Adequate and early penicillin treatment, however, will eliminate streptococci from the throat and prevent most attacks of rheumatic fever.

Diagnosis of Streptococcal Infection

In many instances streptococcal infections can be recognized by their clinical manifestations.

In some patients, however, it is difficult or impossible to determine the streptococcal nature of a respiratory infection without obtaining throat cultures. The following section on diagnosis has been included in order to reduce diagnostic errors and to assist physicians in avoiding unnecessary therapy.

The accurate recognition of individual streptococcal infections, their adequate treatment, and the control of epidemics in the community

presently offer the best means of preventing initial and recurrent rheumatic fever.

COMMON SYMPTOMS

Sore throat—sudden onset, pain on swallowing.

Headache—common.

Fever—variable, but generally from 101° to 104° F.

Abdominal pain—common, especially in children; less common in adults.

Nausea and vomiting—common, especially in children.

COMMON SIGNS

Red throat.

Exudate—usually present.

Glands—swollen, tender lymph nodes at angle of jaw.

Rash—scarlatiniform.

Acute otitis media } frequently due to
Acute sinusitis } the streptococcus.

In the absence of the common symptoms and signs, occurrence of any of the following symptoms is usually not associated with a streptococcal infection: simple coryza, hoarseness, cough.

LABORATORY FINDINGS

White blood count—generally over 12,000.

Throat culture—positive culture for hemolytic streptococci is almost always diagnostic.

Treatment of Streptococcal Infections

When streptococcal infection is suspected, treatment should be started immediately. Penicillin is the drug of choice. Effective blood levels should be maintained for a period of 10 days to prevent rheumatic fever by eradicating the streptococci from the throat.

Penicillin may be administered by either intramuscular or oral route. Intramuscular ad-

ministration is recommended as the method of choice since it insures adequate treatment. Oral therapy by contrast is dependent upon the cooperation of the patient. On the other hand, some physicians and patients prefer repeated oral medication and object to injections.

Recommended Treatment Schedules

INTRAMUSCULAR PENICILLIN

Benzathine Penicillin G

Children—one intramuscular injection of 600,000 units.

Adults—one intramuscular injection of 600,000 to 900,000 units.

or Procaine Penicillin with aluminum monostearate in oil.

Children—one intramuscular injection of 300,000 units every third day for 3 doses.

Adults—one intramuscular injection of 600,000 units every third day for 3 doses.

ORAL PENICILLIN

Children and adults—250,000 units 3 times a day for a full 10 days.

To prevent rheumatic fever by eradicating streptococci, therapy must be continued for the entire 10 days even though the temperature returns to normal and the patient is asymptomatic.

OTHER MEDICATION

It has not been established that the broad spectrum antibiotics are as effective as penicillin in preventing rheumatic fever. They should be used only if the patient is sensitive to penicillin. As with penicillin, the regimen of full therapeutic dosage for a full 10 days should be followed.

The following therapy is not effective in preventing rheumatic fever when used as treatment for streptococcal infections: sulfonamide drugs, penicillin troches or lozenges.

Prevention of Streptococcal Infections in Rheumatic Individuals

Many streptococcal infections occur without producing clinical manifestations. For this reason, prevention of recurrent rheumatic fever

must depend on continuous prophylaxis rather than solely on treatment of acute attacks of streptococcal disease.

Who should be treated?

All individuals who have a well established history of a previous attack of rheumatic fever or chorea or who show definite evidence of rheumatic heart disease should be placed on continuous prophylaxis.

When should prophylactic treatment be initiated?

Active rheumatic fever—As soon as the diagnosis of rheumatic fever is made or any time thereafter when the patient is first seen. The streptococcus should be eradicated with penicillin (see Treatment Schedules) following which the prophylactic regimen is instituted.

Inactive rheumatic fever—In inactive rheumatic fever, prophylaxis should be instituted when the patient is first seen.

How long should prophylaxis be continued?

Throughout life, or until new knowledge makes this recommendation invalid.

Should prophylaxis be continued during the summer?

Yes, continuously. Streptococcal infections can occur at any season although they are more prevalent in the winter.

What are the exceptions to continuous prophylaxis?

Uncertainty as to the validity of a history of a previous attack of rheumatic fever or chorea.
Heart disease of questionable etiology.

In rare circumstances where exposure of the adult patient to streptococcal infection is unlikely.

Prophylactic Methods—Oral and Intramuscular

Oral medication depends on patient cooperation. In most instances failures of sulfonamide or penicillin prophylaxis occur in patients who fail to ingest the drug regularly. This can be avoided by long-acting depot penicillin given intramuscularly once a month.

SULFADIAZINE—ORAL

This drug has the advantage of being easy to administer, inexpensive and effective (other newer sulfonamides are probably as effective). Although resistant streptococci have appeared during mass prophylaxis in the armed forces, this is rare in civilian populations.

Dosage—from 0.5 to 1.0 gm. taken each morning throughout the year. The smaller dose is to be used in children under 60 pounds.

Toxic reactions—infrequent and usually minor. In any patient being given sulfonamides, consider all rashes and sore throats as possible toxic reactions especially if they occur in the first 8 weeks. In patients on this prophylactic regimen it is hazardous to treat toxic reactions or intercurrent infections with sulfonamides. The chief toxic reactions are:

Skin eruptions: Morbilliform—continue drug with caution. Urticaria or scarlatiniform rash associated with sore throat or fever—discontinue drug.

Leukopenia: Discontinue if white blood count falls below 4,000 and polynuclear neutrophils below 35 percent because of possible agranulocytosis which is often associated with sore throat and a rash. Because of these reactions, weekly white blood counts are advisable for the first 2 months of prophylaxis. The occurrence of agranulocytosis after 8 weeks of continuous prophylaxis with sulfonamides is extremely rare.

PENICILLIN—ORAL

Penicillin has the desirable characteristics of being bactericidal for hemolytic streptococci and of rarely producing serious toxic reactions. A careful history of allergic reactions and previous response to penicillin should be obtained.

Dosage—200,000 to 250,000 units once a day, before breakfast.

Toxic reactions:

Urticaria and angioneurotic edema.

Reactions similar to serum sickness—includes fever and joint pains and may be mistaken for rheumatic fever.

Although many individuals who have had reactions to penicillin may subsequently be able to tolerate the drug, it is safer not to use penicillin if the reaction has been severe and particularly if angioneurotic edema has occurred.

BENZATHINE PENICILLIN G INTRAMUSCULAR

Dosage—1,200,000 units once a month.

Toxic reactions—same types as with oral penicillin but occur more frequently and tend to be more severe. Some local discomfort usually experienced.

Protection of Rheumatic Fever Patients in Hospital Wards

Patients with rheumatic fever or rheumatic heart disease are often exposed to increased hazards in hospital wards as the result of contact with streptococcal carriers or patients with active streptococcal infections. Protection of the rheumatic patient is imperative because of the high rate of recurrence of rheumatic fever following streptococcal infection. In addition to the customary precautions employed to prevent cross infections, the following procedures are recommended:

All hospital patients with streptococcal infections should be fully treated by one of the methods outlined in Recommended Treatment Schedules in order to eliminate streptococci and avoid the carrier state.

Patients admitted with acute rheumatic fever should immediately receive a full course of antibiotic therapy, whether or not streptococci are isolated from the throat (see Recommended Treatment Schedules). As soon as the therapeutic course is completed, continuous streptococcal prophylaxis should be instituted (see Prophylactic Methods—Oral and Intramuscular).

Patients with inactive rheumatic fever or rheumatic heart disease should be placed on continuous streptococcal prophylaxis on admission to the hospital or as soon thereafter as the diagnosis is established (see Prophylactic Methods—Oral and Intramuscular).

Prophylaxis Against Bacterial Endocarditis

In individuals who have rheumatic or congenital heart disease, bacteria may lodge on the heart valves or other parts of the endocardium, producing bacterial endocarditis. Transient bacteremia which may lead to bacterial endocarditis is known to occur following various operative procedures including dental extractions and other dental manipulations which disturb the gums, the removal of tonsils and adenoids, the delivery of pregnant women, and operations on the gastrointestinal or urinary tracts. It is good medical and dental practice to protect patients with rheumatic or congenital heart disease by prophylactic measures.

Recommended Prophylactic Methods

Penicillin is the drug of choice for administration to patients with rheumatic or congenital heart disease undergoing dental manipulations, or operative procedures in the oral cavity.

Although the exact dosage and duration of therapy are somewhat empirical, there is some evidence that for effective therapeutic prophylaxis reasonably high concentrations of penicillin must be present at the time of the operative procedure. The dosage regimens employed for long-term prophylaxis of rheumatic fever are inadequate for this purpose. There is reason to believe that continuous maintenance of penicillin in the blood over a period of several days will result in the death of those organisms which have lodged in the heart valve during the period of transient bacteremia.

Not only should penicillin prophylaxis be designed to afford maximum protection, but the method must also be practical. In general, the parenteral route of administration is preferred. All patients should be instructed to report to their physician or clinic should they develop a fever within a month following the operation.

INTRAMUSCULAR PENICILLIN

Dosage—600,000 units of aqueous penicillin and 600,000 units of procaine penicillin in oil containing 2 percent aluminum monostearate administered intramuscularly 30 minutes before the operative procedure.

ORAL PENICILLIN

As an alternative, although considered less desirable, penicillin may be administered by the oral route.

Dosage—250,000 to 500,000 units one-half hour before each meal and at bedtime, beginning 24 hours prior to the operation and continuing for 5 days. At the time of the operative pro-

cedure it is advisable to give an additional 250,000 units.

Contraindications—Patients who give a history of sensitivity to penicillin.

OTHER ANTIBIOTICS

The broad spectrum antibiotics should be employed as prophylaxis in patients who are sensitive to penicillin or in those who are undergoing surgery of the urinary or lower gastrointestinal tract. Oxytetracycline, chlortetracycline, or erythromycin should be administered in full dosage for 5 days, beginning treatment the day prior to the surgical procedure.

Public Education Materials

Education materials for the general public on rheumatic fever prevention include:

A 12½-minute, 16-mm. film, entitled "Stop Rheumatic Fever," produced by Transfilm, Inc., for the National Heart Institute with the cooperation of the American Heart Association.

A new booklet for adults, "Stop Rheumatic Fever," summarizing the film content and illustrated with stills from the film. The booklet tells about streptococcal infections and what to do about them to prevent rheumatic fever and rheumatic heart disease.

A discussion guide to aid users of the film and

other educational material in arranging programs for parents, teachers, and community health meetings.

A pamphlet, entitled "Now You Can Protect Your Child Against Rheumatic Fever," which features a chart advising on "when to call the doctor and what to tell him about your child's sore throat."

A question-and-answer leaflet presenting background information on rheumatic fever.

These materials are available from local heart associations and health departments as well as from the American Heart Association, 44 East 23d Street, New York 10, N. Y., and the Heart Information Center, National Heart Institute, Public Health Service, Bethesda 14, Md.

Infective Larvae of *Ancylostoma caninum*

16 mm., sound, black and white, 4 minutes, 157 feet. 1954.

Audience: Parasitologists, students of parasitology and biology, and others interested in the study of intestinal parasites.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

Infective larvae of the dog hookworm is the subject of this motion picture, which has been filmed especially for parasitologists and students of parasitology and biology. It shows the migration upward from beneath the surface of the soil of large numbers of infective hookworm larvae. Another phase of the larva behavior pictured is the vertical position assumed on soil particles, either singly or in tufts composed of dozens of worms.

Ancylostoma caninum in the Intestine of the Dog

16 mm., sound, black and white, 5 minutes, 184 feet. 1954.

Audience: Parasitologists, students of parasitology and biology, and others interested in the study of intestinal parasites.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

Bloodsucking activities and copulation of adult hookworms in the intestine of the dog are featured in this motion picture. The hookworm species *Ancylostoma caninum* is used in the demonstration. Characteristics of the parasite shown are the large numbers of living hookworms

***Ancylostoma caninum* in the
intestine of the dog**

able to attach themselves to the intestinal mucosa; the worms ingesting blood and eliminating it from their posterior end; and the continued feeding of the parasites while the male and female are in copula. The amount of blood lost by the host through the feeding of a single worm is an interesting depiction.

An Outbreak of *Salmonella* Infection

16 mm., sound, black and white, 13 minutes, 481 feet. 1954.

Audience: Pathologists, nutritionists, dietitians, sanitarians, and others interested in foodborne disease control.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

A simulated case study of foodborne illness is used in this motion picture to illustrate to viewers the problems caused by an outbreak of foodborne infection. Organisms of the *Salmonella* group have been chosen for this demonstration of typical food contaminants.

The film depicts the sources of *Salmonella* organisms; factors contributing to the survival and transfer of the organisms; and ways in which contamination may occur. It describes an illness outbreak in terms of persons exposed to and susceptible to the infection. Recommended

methods for sanitary food handling under ordinary circumstances are shown.

Transmission of Anthrax— Animal to Man

35 mm. filmstrip, sound, color, 12 minutes, 70 frames. 1954.

Audience: Pathologists, physicians, medical students, and others interested in disease transmission control.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

Using both artists' sketches and clinical photographs, this filmstrip traces the history of anthrax from the time of the Pharaohs to the present, emphasizing particularly the work of Chabert, Koch, and Pasteur. It shows how anthrax spores are brought into the United States on imported animal products such as wool, hair, and hides; and how human anthrax infection generally can be traced to diseased cattle, sheep, or swine in rural areas and to animal products used by industry.

A healing anthrax lesion

The appearance of anthrax lesions and response to clinical treatment are demonstrated in pictures of several cases of human anthrax.

On maps is shown the distribution in the United States of human and of animal anthrax during 1953; and on a bar chart is indicated the number of reported cases of human anthrax in the United States for the years 1944 to 1953.

An important new development in the serodiagnosis of syphilis is the demonstration of at least two Treponema pallidum agglutinating antibodies in syphilitic serums.

Agglutination of *Treponema pallidum* by Reagin Antibody

By CHARLOTTE P. McLEOD, Sc.D., and PEGGIE S. STOKES, A.B.

SPECIFIC AGGLUTINATION of killed *Treponema pallidum* has been demonstrated by several investigators (1-3). Recently, McLeod and Magnuson (4) showed that agglutination of *T. pallidum* in syphilitic serum was greatly enhanced by the coagulating action (5) of fresh steer serum. A preliminary evaluation (4) of this technique as a diagnostic test for syphilis indicated that the comparatively simple agglutination test might be as sensitive and specific as the *T. pallidum* immobilization (TPI) test (6). Subsequent experiments, however, have made clear that the agglutination test in its present form detects more than one antibody and is in part a measure of reagin. These investigations, together with

a study of certain factors which influence the sensitivity of the test, are the subject of the present paper.

Methods

The methods used were similar to those earlier described in detail (4). Spirochetes were extracted in saline from testicular lesions of rabbits inoculated 7 to 10 days earlier with the Nichols strain of *T. pallidum*. The organisms were sedimented by centrifugation, resuspended in fresh saline, and the suspensions adjusted to contain approximately 60 to 75 spirochetes per high-power field. In order to insure even distribution of the organisms, bovine albumin fraction V was added in a final concentration of 5 percent. The antigens were then heated at 56° C., unless otherwise stated, and stored at -20° C.

Serum samples to be tested were similarly stored at -20° C. Steer serum was stored in a CO₂ chest at -76° C. and was not thawed until immediately before use. The same lot of steer serum was employed in all experiments. It was titrated for natural agglutinins against each new antigen, and the lowest dilution which did not agglutinate the spirochetes was used in the test (1:7 to 1:15 dilution).

In performing the tests, the antigen was pre-

Dr. McLeod is a bacteriologist and Mrs. Stokes is a research assistant with the Venereal Disease Experimental Laboratory, Public Health Service, at the School of Public Health, University of North Carolina, Chapel Hill, N. C.

Results of the TPI tests were supplied by George Cannefax, who is also with the Venereal Disease Experimental Laboratory.

This paper was presented at the Symposium on Recent Advances in the Study of Venereal Diseases, Washington, D. C., April 29, 1954.

Table 1. Effect of absorptions with VDRL antigen on the agglutinating titer of syphilitic serum

Added to tests	Agglutinating titers ¹			
	Control pool B (VDRL 1:32)		Absorbed pool B (VDRL negative)	
	10 minutes	2 hours	10 minutes	2 hours
Saline--- Steer serum.	Negative-- 1:80-----	1:40 1:160	Negative-- Undiluted--	Undiluted. 1:40.

¹ Antigen heated at 56° C. for 40 minutes.

sensitized by the antibody before adding the steer serum, and parallel tests were run without steer serum. One-tenth cubic centimeter of antigen was mixed with 0.1 cc. of test serum or dilution in Wassermann tubes and the mixtures were shaken for either 2 or 23 hours. One-tenth centimeter of steer serum or saline was then added and the tubes were shaken for an additional 10 minutes. The tests were shaken on a standard Kahn shaker, or on a much less vigorous shaker with a rotary motion (250 revolutions per minute, 1-inch diameter). The tests were incubated either at room temperature (21° to 24° C.) or in an incubator at 33° to 35° C. Although agglutination occurred more rapidly on the Kahn shaker, the titers obtained in 2 hours on the positive control syphilitic serum pool B were similar on both shakers and were unaffected by the temperature of incubation. The method of reading the tests has been described (4). In the present study, titers are expressed as the lowest dilution which showed strongly positive agglutination (3+ to 4+).

Nonsyphilitic serum containing reagin antibody was produced by the method of Eagle (7) in normal rabbits whose serum initially showed negative VDRL (8) and agglutination tests. The animals were injected with saline suspensions of washed lipoidal antigen-antibody precipitate obtained by absorbing human syphilitic serum with VDRL antigen. (Twenty-five cubic centimeters of serum, VDRL titer 1:8, were absorbed once with the washed sediment from 125 cc. of antigen. Thirty cubic centimeters of serum, VDRL titer 1:64, were

absorbed three times with sediment from a total of 525 cc. of antigen.) Each dose was contained in a volume of 5 cc. Five rabbits were inoculated intraperitoneally with 5 doses each during a period of 13 days and were bled on the day following the last injection.

Results

A first experiment showed the presence of at least two agglutinating antibodies in syphilitic serum. A portion of human syphilitic serum pool B, which contained both reagin and TPI antibodies, was absorbed with VDRL antigen until a negative VDRL slide test was obtained. The agglutination titers of the control serum and of the reagin-absorbed serum were then compared in a test with antigen which had been heated at 56° C. for 40 minutes. The tests were read after incubation periods of 10 minutes and 2 hours.

The results, shown in table 1, indicate that a part of the agglutinating activity of pool B was due to the presence of reagin. This is shown most clearly at 10 minutes in the test with steer serum, and at 2 hours in the test without steer serum. In the test with steer serum, control pool B (VDRL 1:32) showed an agglutination titer of 1:80 at 10 minutes whereas absorbed pool B (VDRL negative) agglutinated only when undiluted. In the 2-hour test without steer serum, the titer of pool B was 1:40, whereas absorbed pool B agglutinated only when undiluted. The presence of another agglutinating antibody, not identical with reagin, was demonstrated in absorbed pool B in the test with steer serum. The absorbed serum contained no meas-

¹ Antigen heated at 56° C. for 40 minutes.

urable reagin but had an agglutination titer of 1:40 at 2 hours.

In a second experiment it was shown that *T. pallidum* was agglutinated by reagin antibody in nonsyphilitic serum. Five normal rabbits were immunized with lipoidal antigen-antibody precipitate as described under "Methods," and the serum from these animals was tested for the presence of reagin, agglutinating, and TPI antibodies. The agglutination tests were run with steer serum, using antigen heated at 56° C. for 40 minutes, and were read at 2 hours. The titers obtained in the three tests are shown in table 2. All of the serums gave positive VDRL and agglutination tests but negative TPI tests. The VDRL titers ranged from 1:32 to 1:128, and the agglutinating titers ranged from undiluted to 1:160. Three rabbits were high in both VDRL and agglutinating titers. In the two rabbits with low titers, the VDRL test appeared to be a more sensitive test for reagin than the agglutination test.

A study was next made of the effect of the length of the incubation period on the agglutinating titer. The serum samples from the five rabbits immunized with VDRL antigen-antibody precipitate were pooled and designated "nonsyphilitic reagin serum." Agglutination tests were run on this serum, which contained only reagin antibody; on pool B, which contained reagin and at least one additional antibody; and on absorbed pool B, from which the reagin antibody had been removed. The tests were run with antigen which had been heated at 56° C. for 40 minutes and were read after incubation periods of 2 and 23 hours. The results are shown in table 3.

The nonsyphilitic reagin serum (VDRL 1:64) showed no rise in titer on prolonging the incubation period from 2 to 23 hours. In the test with steer serum, pool B (VDRL 1:32) also showed no rise in titer after 2 hours. On the other hand, absorbed pool B (VDRL negative) showed a fourfold rise in titer between 2 and 23 hours. This slow rise in titer of the second antibody apparently was masked, or partially masked, in control pool B by the rapid agglutinating action of the reagin antibody. The addition of steer serum caused no rise in the titer of the nonsyphilitic reagin serum either at 2 or at 23 hours. In both the control and the absorbed pool B, the addition of steer serum caused a rise in titer at 23 as well as at 2 hours.

The effect of heat on the sensitivity and specificity of the antigen was investigated. In preparing the antigens for these studies, aliquot portions of the same spirochete suspension were used. One portion was not heated; a second portion was heated at 56° C. for 40 minutes, and a third portion was heated at 100° C. for 40 minutes.

The sensitivity of these antigens was tested in a first experiment with control pool B and with pool B which had been absorbed with VDRL antigen; and in a second experiment, with the nonsyphilitic reagin serum. The tests were read after an incubation period of 2 hours, with results which are illustrated in table 4. The titers of each of the three serums increased both with and without steer serum as the antigens were heated. Heating the antigen at 100° C. increased its sensitivity to the reagin antibody, as shown by the titers of the nonsyphilitic

Table 4. Effect of heat on agglutinability of antigen in syphilitic serum and in nonsyphilitic reagin serum

Serum tested	Added to tests	Agglutinating titers at 2 hours		
		Antigen not heated	Antigen heated, 56° C., 40 minutes	Antigen heated, 100° C., 40 minutes
Experiment 1:				
Pool B (control)-----	Saline-----	1:10-----	1:40-----	1:160
	Steer serum-----	1:20-----	1:320-----	1:1,280
Pool B (absorbed)-----	Saline-----	Undiluted (3+)-----	Undiluted (4+)-----	1:10
	Steer serum-----	Undiluted (4+)-----	1:80-----	1:320
Experiment 2:				
Nonsyphilitic reagin serum-----	Saline-----	Negative-----	1:20-----	1:40
	Steer serum-----	do-----	1:20-----	1:320

reagin serum, and to the second antibody as shown by the titers of the reagin absorbed syphilitic serum. Heating the antigen at 100° C. also markedly increased its sensitivity to the conglutinating action of steer serum. This is shown most clearly in the tests with the non-syphilitic reagin serum. The addition of steer serum caused no rise in titer with the antigen heated at 56° C., but caused an eightfold rise with antigen heated at 100° C.

In testing the effect of heat on the specificity of the antigen, agglutination tests were run on serum samples from 19 individuals with negative VDRL and TPI tests (medical students and laboratory personnel). The undiluted serum from each donor was tested both with and without steer serum against antigen heated at 56° C. for 40 minutes and against antigen heated at 100° C. for 40 minutes. The tests with antigen heated at 56° C. were read after incubation periods of both 2 and 23 hours. The tests with antigen heated at 100° C. were read at 23 hours. Since approximately the same findings were obtained on each serum both with and without steer serum, the results of the two techniques have not been tabulated separately. The numbers of serums showing positive or negative agglutination with each antigen are listed in table 5.

With antigen heated at 56° C., 18 of the 19 normal serums were negative at 2 hours and 1 was weakly positive (1+). At 23 hours, 7 serums remained negative, and 12 were weakly

positive. With antigen heated at 100° C., only 1 serum was negative at 23 hours. Of the 18 samples showing agglutination, 3 were weakly positive (2+) and 15 gave strongly positive reactions (3+ to 4+).

Discussion

The experiments show that the utilization of the agglutination technique as a diagnostic test for syphilis must await the preparation of more specific antigens. The test with heat-killed spirochetes measured at least two different antibodies in syphilitic serum. One antibody

Table 5. Effect of heat on agglutinability of antigen in undiluted normal human serum

Agglutination test procedure	Total serums tested ¹ (TPI negative, VDRL negative)	Results of agglutination test		
		Negative	1+, 2+	3+, 4+
Antigen heated at 56° C.:				
Incubated 2 hours---	19	18	1	0
Incubated 23 hours--	19	7	12	0
Antigen heated at 100° C.:				
Incubated 23 hours--	19	1	3	15

¹ Each serum was tested with and without steer serum, with similar results.

showed rapid agglutinating activity and was proved to be reagin. The second antibody acted more slowly and has not been identified. Its possible identity with the TPI antibody will be the subject of a later report.

The mechanism by which steer serum enhances agglutination has not been explained. With the reagin antibody, the reaction appeared to be accelerated. The reagin titer was higher with steer serum in tests read at 10 minutes, but no enhancement was obtained after an incubation period of 2 hours. On the other hand, in experiments with syphilitic serum from which reagin had been removed, steer serum enhanced agglutination after an incubation period of 23 hours. Whether this effect was due to an increased sensitivity of the test or to the participation of more than one antibody has not been determined. These problems, together with the preparation of more efficient antigens, are under continued study.

Summary

The presence of at least two agglutinating antibodies was demonstrated in syphilitic serum. One antibody agglutinated rapidly and was identified as reagin. The identity of the other, more slowly acting, antibody has not been determined. The sensitivity of the antigen increased in proportion to the temperature at

which it was inactivated. Heating the antigen at 100° C. markedly decreased its specificity.

Physicians in Public Health

By LEONARD S. ROSENFELD, M.D., M.P.H.
and MARION E. ALTENDERFER, B.A.

PUBLISHED DIRECTORIES and listings accumulated by several professional organizations and health agencies give only partial or noncurrent information on the number and characteristics of physicians who devote full time to public health activities. All such listings have been prepared for some specific purpose which in no case encompasses that of providing a complete inventory of full-time public health physicians.

The purposes of the present study were to obtain as complete a count as possible of physicians engaged full time in the field of public health; to analyze their characteristics, qualifications for public health work, and geographic distribution; and to ascertain their medical school background. This paper covers the first two of these purposes.

Prerequisite to making such a study was the adoption of a definition of public health. Although not providing specific criteria for selection of physicians, the broad and widely accepted concept of public health as organized

community effort for "preventing disease, prolonging life, and promoting physical and mental health and efficiency," expressed by Dr. C.-E. A. Winslow (1), seemed the most useful. With this definition, it was possible to establish a broad requirement for inclusion in the study, that is, service in preventive medicine as a teacher, an administrator, a research investigator, or a practitioner in governmental or organized voluntary activities, as contrasted with service in clinical medicine or independent practice.

As will be shown in the discussion of the available sources of information, decisions with regard to the inclusion or exclusion of individual physicians had to be fairly arbitrary, and the list compiled is admittedly incomplete. Nevertheless, the accumulation of a total count of almost 3,500 full-time public health physicians and the analysis of data on their distribution by age, position, and geographic location are believed to be a useful start toward more definitive and detailed studies.

Materials and Method

The primary sources used in the study were the following:

1. The list of diplomates of the American Board of Preventive Medicine in the 1951 edition of the Directory of Medical Specialists (2) plus a list of physicians who received their certificates in 1951, the latter obtained from the files of the secretary of the board.
2. The 1951 Directory of Full-Time Local Health Units (3).

Dr. Rosenfeld, now director of medical care evaluation studies, United Community Services of Metropolitan Boston, was chief of the Health Profession Education Branch, Division of Public Health Methods, Public Health Service, when this study was made. Miss Altenderfer is a statistician in the Division of Public Health Methods. Other members of the division who assisted in preparing the report are Dr. Leslie Knott, Martha D. Ring, and Kathryn I. Baker.

3. The 1951 Directory of State and Territorial Health Authorities (4).

4. Information on full-time faculty members in schools of public health obtained in a 1950 survey of these schools (5).

5. A list of physicians with regular or active reserve commissions in the Public Health Service who were engaged in nonclinical work in 1951.

6. Information on full-time faculty members in departments of preventive medicine obtained by the Office of Defense Mobilization in its 1951 survey of medical school faculties.

7. Schedules listing full-time health department personnel collected by the Division of State Grants, Public Health Service, in a study made for the National Security Resources Board in 1951.

8. Lists furnished by the Army, Navy, and Air Force of personnel giving full time to preventive medicine and public health in 1951 (Air Force data are for 1953).

None of these sources gives a complete picture of all physicians engaged full time in public health work. The following limitations on the inclusiveness of the listings should be noted.

The roster of diplomates of the American Board of Preventive Medicine does not include all physicians in public health because many of them lack the requisite 6 years of special training, teaching, or practice in preventive medicine. Furthermore, the board was established only in 1948, and many eligible physicians have not yet applied for certification. The diplomates, therefore, represent only the more experienced physicians in the field of public health.

Reports of the number of physicians employed full time in State and local departments and other non-Federal governmental agencies, of course, give no indication of the number in other types of organizations. Numerous physicians engaged in public health work are employed by voluntary agencies and foundations.

Since the Public Health Service, the Army, the Navy, and the Air Force are responsible for a wide range of operations in the field of medicine, it was necessary to separate the physicians concerned primarily with public health from those concerned primarily with clinical medicine. For Public Health Service person-

nel, all physicians with a Regular or Active Reserve Corps commission engaged in non-clinical work were included, whether in the Public Health Service or detailed to other Federal agencies. For the other services, groups of physicians working full time in various branches of preventive medicine were selected, after a review of the classification maintained in each service, on the basis of both qualifications and nature of assignment. None of these services was able to furnish a complete listing of physicians giving full time to preventive medicine.

Other Federal agencies—such as the Children's Bureau, Department of Health, Education, and Welfare; the Veterans Administration; and the Atomic Energy Commission—which employ a number of public health physicians, were not asked for lists. Some of their public health physicians are included, however, because they are commissioned officers of the Public Health Service or because they are diplomates of the American Board of Preventive Medicine. For example, almost two-thirds of the regional medical directors and the physicians on the headquarters staff of the Children's Bureau are diplomates.

In addition to the 8 primary sources of information, 3 secondary sources were used to supply biographical data: the 1950 American Medical Directory (6), the 1951 Membership Directory of the American Public Health Association (7), and lists of physicians awarded public health degrees by approved schools of public health.

Physicians listed only in the secondary sources were not included in the study, for various reasons. There is no assurance, for example, that all 1,567 physicians listed in the 1950 American Medical Directory as limiting their practice to public health were actually in the public health field at that time. This directory is based on cards mailed to all physicians; the number of physicians who failed to return the card and for whom, therefore, the directory information is not current is unknown. The Directory of the American Public Health Association includes foreign physicians, physicians engaged only part time in public health, and physicians with an interest in public health, as well as those devoting full time to the field.

Because the major sources of information provided data for 1951, an effort was made to obtain data from other sources relating as closely as possible to that year.

In collating the information from the several primary sources, the following procedure was used: The names of all diplomates of the American Board of Preventive Medicine were first entered on cards. These cards were alphabetized and checked against the directories of State and local health departments; a card was then made for each additional physician listed in these directories. In like manner, cards were added for physicians listed in the other primary sources. Of the 3,484 physicians included in the study, 29 percent were obtained from the list of diplomates; 27 percent from the directories of State and local health departments; 25 percent from the special study of health department personnel; 14 percent from the list of Public Health Service commissioned officers; and 5 percent from the other sources.

The card for each physician contained as much of the following information as could be obtained: name; State and city in which located; year of birth; medical school; year of graduation; specialty board certification, if any; present position; degree in public health, if any; school from which degree in public health was obtained; date of degree in public health; specialty, if indicated in the American Medical Directory.

Type of Position

In 1951, an estimated 3,441 physicians were engaged full time in some phase of public health work. Almost half (48 percent) of them were in local health departments. The next largest group (18 percent) comprised the commissioned officers of the Public Health Service. An additional 17 percent were in State and Territorial health departments. Physicians in Federal positions other than the Public Health Service

Figure 1. Age distribution of public health physicians by type of position, 1951.

accounted for 7 percent; those engaged in teaching, for 5 percent; and those working in State and local governmental agencies other than health departments, for 1 percent. The remaining 4 percent were in hospitals, voluntary agencies or foundations, or "other positions." In addition to the physicians engaged full time in public health, 4 physicians in private practice, 16 who were retired, and 23 for whom the present position was unknown are included, giving a grand total of 3,484 physicians. The physicians in the "all other" category and those not actually working in public health are included because they are diplomates of the American Board of Preventive Medicine.

Age Distributions

Analysis of the physicians in public health by position and age brings out some interesting relationships. Of the 641 physicians under 35 years of age, 309, or 48 percent, are in the Public Health Service. At the other end of the age scale, 75 percent of the 412 physicians 65 years of age and over are in local health departments.

The distribution by age of physicians in different types of public health positions is shown in table 1 and figure 1. Although the proportions in each age group vary somewhat, the

age patterns are similar for physicians in State health departments, local health departments, and other State and local governmental agencies. For each of these, the largest proportion of physicians is in the 45-54 age group. The age distribution for physicians in full-time teaching positions differs in several respects from the distribution for physicians in those positions: The largest proportion of teachers is in the 35-44 age group, and the proportion in the youngest and oldest age brackets is smaller.

The percentage distribution by age of physicians in State and local health departments in the United States is shown separately in table 2. The proportion of physicians who are 55 years of age or over is substantially larger in local health departments (40 percent) than in State health departments (26 percent). This is attributable to two factors. First, physicians in positions other than that of health officer tend to be younger than the health officer. For example, 24 percent of local health officers are 65 years of age or over but only 11 percent of other physicians in local health departments are in this age group. Second, health officers account for 60 percent of physicians in local health departments but for only 9 percent of those in State health departments.

The distribution of all non-Federal physicians by region in relation to the population distribution is shown below :

	<i>Non-Federal public health physicians (percent)</i>	<i>1951 civilian population (percent)</i>
United States-----	100	100
Northeast-----	25	26
North Central-----	21	30
South-----	38	31
West-----	16	13

The Northeast and the West have about the same proportion of public health physicians and of population. The North Central region has a considerably lower proportion of public health physicians than of population, and in the South the reverse is found.

Graduate Degrees

Of the 3,484 public health physicians included in the study, 1,232 (35 percent) have one or more graduate degrees (table 4). Among the physicians with graduate degrees, 1,042 have a master's degree or certificate and 190 have a doctorate degree. The majority of those with master level training have a degree in public health, but a few hold a master of science or a master of arts degree. At the doctorate level, 139 hold the degree of doctor of public health, 38 are doctors of philosophy, and a few have other doctorates.

The proportion of physicians with graduate degrees varies considerably from one type of position to another. While 46 percent of all physicians in State health departments have graduate degrees, 73 percent of State health officers and only 43 percent of other physicians in State health departments have such degrees. The proportion with graduate degrees is high among public health physicians in teaching positions, in "other Federal" positions, and in "all other" positions. The lowest proportion is among the physicians in agencies of State and local government other than health departments. The comparatively low proportions of Public Health Service physicians with graduate degrees may be partly accounted for by the high proportion (49 percent) of physicians under 35 years of age in this group.

The number of physicians in each age group

Figure 2. Public health physicians with or without graduate degrees by age group, 1951.

with and without graduate degrees is shown in figure 2. In the group 65 years of age and over, 11 percent have a graduate degree; in the youngest age category, the proportion is 15 percent; for those aged 55-64 years, the proportion increases to 31 percent; in the two age groups 35-44 years and 45-54 years, 51 and 49 percent, respectively, have graduate degrees. The relatively low percentage of older physicians with public health degrees may be attributed to the fact that opportunities for graduate training in public health were limited until the late 1930's. The number of physicians with doctorate degrees is very small for those under 35 years of age, greater for those 65 years and over, and greatest for physicians in the middle age brackets.

Substantial differences are found among the four regions of the country in the proportion of State and local health department physicians with graduate degrees or with specialty quali-

fications in preventive medicine (table 5). As may be expected, the proportion of physicians with degrees closely parallels the proportion with specialty qualifications. These characteristics, in turn, are correlated with the proportion of physicians between 35 and 54 years of age. The West, with the highest proportion of physicians in this age group, has the highest proportion with graduate degrees or with specialty qualifications. The South, with the lowest proportion of public health physicians in the 35-54 age group, has the lowest proportion of physicians with these qualifications. In general, roughly the same relationships hold when characteristics of physicians in State and local agencies are examined separately.

Specialization

Twenty-nine percent of the public health physicians in the study are diplomates of the Amer-

ican Board of Preventive Medicine (table 4). Again great variation appears among physicians in different types of positions. Physicians in "all other" positions are all diplomates—the reason for their inclusion in the study. State health officers have the highest proportion of diplomates (79 percent); physicians below the health officer level in local health departments, the lowest proportion (10 percent).

Of the 1,008 physicians who are diplomates of the American Board of Preventive Medicine, 66 also hold a certificate from another American board. In addition, 178 other physicians in the study are diplomates of other specialty boards—48 of pediatrics, 37 of internal medicine, 27 of psychiatry and neurology, 20 of pathology, and a few each of 9 other boards. In some instances this specialization indicates a shift in interest or in type of practice from the designated specialty to public health. In other instances a physician employed full time in a health de-

Pennsylvania-----	1951	B.S.E., M.P.H.-----	The executive office.
Virginia-----	1954?	M.D.-----	Director of local health.

¹ Information incomplete.

² Position vacant.

training is the question of whether a State sends most or all of its new workers to one training station or disperses them among several. At one time thinking favored a single training center, but the current shifted.

In 1950, after 2 years of study, California changed to the use of dispersed stations, that is, several good local departments able and willing to receive several trainees in one or more fields. In reaching the decision it was felt that (*a*) several centers together could train more workers than one station, (*b*) quality did not suffer, (*c*) local interest was stimulated, and (*d*) cost was less.

Today, Florida and Texas are apparently the only States relying on a single training center. An exception exists with sanitarians, for whom the Communicable Disease Center of the Public Health Service has for some time maintained regional training centers.

When a local department is used for State training purposes, some special aid is usually extended by the State. This may be in the form of a lump sum increase in State aid, or of payment of a fee for each trainee, or of the assignment of extra personnel to the local staff.

Of the States with full-time directors of training, three States—California, Louisiana, and Massachusetts—have been stimulated and aided in development of training by grants from private foundations, either the Kellogg Foundation or the Commonwealth Foundation. Other States, including Michigan, Oklahoma, Tennessee, Texas, and Washington, have also had such aid. The laying of much of the groundwork in training was evidently due to this help from pioneering private agencies.

In California, Indiana, New York, Massachusetts, Michigan, and Ohio, the training office has also some responsibility in recruiting health workers for the department.

While schools of public health are active in formal training of health workers, many schools also contribute in a greater or lesser degree to extramural training or continuation education in the State or region where the school is located. Several schools of public health nursing also offer extension courses.

Some State departments of health are fortunate in receiving distinct aid in training from a nearby university. New Jersey has long been helped by Rutgers University, in both formal and short courses. Kansas, Kentucky, and Oklahoma also depend strongly on the State university. For a decade Florida has offered home study courses to local water works and sewage plant operators. Michigan in 1950 established the policy (*3*) of "limiting the department's sponsorship of training to those fields where the established educational institutions are unable to provide service." This expresses what most States are now doing. In Illinois the department of public health and the university conduct four correspondence courses in sanitation.

Recommendations

Statistical evaluations in so wide a field are difficult, but as a result of this study my personal recommendations are as follows:

Training is a normal function of administration and should include service from the State to localities.

Every State department of health should have a training committee, preferably with members from local departments and from educational institutions whose major concern is with training policies.

Every State department of health should have one person designated as director or coordinator of training. In most States, he will devote part of his time to training and will be selected both for his interest in training and for the related nature of his other duties. In States with a larger number of State or local health workers, he should give his full time to training. Whether on a part-time or full-time basis, this person should work with others who will themselves do the actual training. He should use educational institutions wherever possible. He should preferably be a physician. His position in the department should be high enough to

exert influence. He should work and plan with the confidence that the ground swell is setting his way (4).

PHS Staff Announcement

Dr. Clifton K. Himmelsbach was appointed chief, Division of Hospitals, Public Health Service, in March 1955. As chief of the division, he will have charge of all Public Health Service hospitals and outpatient clinics. With the Service since 1931, Dr. Himmelsbach had been assistant chief of the division until his recent appointment. Before then, 1948-53, he was in charge of the Washington, D. C., outpatient clinic, and,

earlier, chief of the Medical Operations Branch of the Federal Employee Health Program.

Included under Dr. Himmelsbach's direction is the Lexington, Ky., hospital for the treatment of narcotic addicts. At one point in his career, when he was assigned to the research branch of that hospital, Dr. Himmelsbach directed clinical investigations on the nature and quantification of narcotic addiction and the methods for detection of addiction liability in new drugs.

Studies on Dental Care Services for School Children

—Third and Fourth Treatment Series, Woonsocket, R. I.—

By FRANK E. LAW, D.D.S., M.P.H., CARL E. JOHNSON, D.D.S.,
and JOHN W. KNUTSON, D.D.S., Dr.P.H.

THE WOONSOCKET dental care study was designed to provide factual information on the problems of accumulated and maintenance dental service needs of school children in a fairly representative New England industrial town. Complete dental care, exclusive of orthodontics, was furnished all children enrolled in kindergarten through the ninth grade, provided treatment was requested by a parent or guardian. This long-term study, a cooperative project of the city of Woonsocket, the Rhode Island State Department of Health, and the Public Health Service, consisted of four consecutive treatment series. Study participants received in the course of each series an examination, a prophylaxis, topical fluoride applications, and treatment of dental defects. Data describing the organization and operation of the program and the results of the first and second treatment series have been previously reported (1). Performance

data descriptive of the third and fourth series are the subject of the present paper.

Review of First Two Series

Examination findings disclosed that 84 percent of the participants in the first series had 1 or more permanent teeth needing filling; 22 percent had at least 1 missing permanent tooth; and 20 percent had 1 or more filled permanent teeth. In the 30 months required to complete the first series, the average child received 3.3 dentist man-hours of care. An average of 2.1 permanent teeth were treated per dentist man-hour.

Of children taking part in the second treatment series, 87 percent had 1 or more carious permanent teeth; 18 percent had 1 or more extracted permanent teeth; and 58 percent had at least 1 filled permanent tooth. The second series extended over a period of 24 months, with an average of 2.8 dentist man-hours devoted to each child. The number of permanent teeth treated per dentist man-hour averaged 1.9.

Followup Program

A followup program for children whose parents had not requested treatment in the school

Dr. Law is regional dental consultant for Region III, Department of Health, Education, and Welfare; Dr. Johnson is a member of the staff of the Public Health Service Outpatient Clinic in New York City; and Dr. Knutson is chief dental officer of the Public Health Service.

clinic program was operated throughout the four series. Consisting largely of conferences with teachers and home visits, the program aimed at encouraging these parents to take their children to a private dentist regularly. Approximately 6 percent of the school population received care in private dental offices. Ten percent of the children would not accept treatment from any source during the period covered by this program.

Clinic Routine

At the beginning of each series, teachers distributed "request for treatment" forms to all children regardless of whether or not they had previously participated in the study project. In each school, the entire student body was examined prior to the beginning of treatment. Every effort was made to keep the sequence of schools the same in all treatment series.

The first series was devoted exclusively to the correction of accumulated dental needs. The following rounds represented, therefore, a periodic treatment of accruing, or incremental, defects. For example, the fourth treatment series consisted largely of treatment of dental defects which had arisen since completion of the third, or preceding series. In addition to incremental defects, however, there was a continuing backlog of dental care needs reflecting

the new enrollment of children in school during each series. In the third treatment series, 1,123 children, or 23 percent of those receiving clinic care, fell into this category. In the fourth series, the 950 newly enrolled children constituted about one-fifth of the entire group treated in school clinics.

To measure and express the work load accurately, all teeth needing fillings, whether or not they had previously been filled, were counted as "carious." Also rated as carious were teeth indicated for extraction. The examination, recording, and treatment procedures utilized in the first two series (1) were continued throughout the program.

This report, like that on the first two series, is basically concerned with dental care services. Consequently, baseline and performance data apply only to those children participating in the school clinic program.

During the third treatment series, 5,975 children, or 98 percent of those enrolled in kindergarten through the ninth grade, were examined. Treatment was provided 82 percent of this group. In the fourth series, 6,201 children, or more than 99 percent of the school population, were examined. Of this group, 81 percent subsequently received dental treatment. The age distribution of children examined and their patient status for the final two treatment series are shown in table 1.

Table 1. Age distribution of all children examined, by patient status, third and fourth treatment series, Woonsocket, R. I.

16-----	22	18	40	28	16	44

Caries Prevalence

The annual increment of decayed permanent teeth, estimated from the difference in prevalence rates at individual ages, averaged 1.3 teeth per child. The proportion of children with one or more carious permanent teeth declined from 87 percent in the second round to 77 percent and 65 percent in the third and fourth rounds, respectively.

Age-specific rates for filled permanent teeth in the third series ranged from 0 at age 5 to 10.47 at age 15; in the fourth, from 0 to 11.18 for the same age groups (table 2 and figs. 1 and

2). At the beginning of the first series the corresponding rates were 0 to 2.33 teeth per child. For all age groups, the average frequencies for carious and missing permanent teeth per child dropped steadily from the first to the fourth series (table 3). At the same time, the number of filled teeth per child increased from 1.32 in the first series to 5.63 in the fourth. Only 20 percent of the children had one or more filled permanent teeth at the start of the program. In the third and fourth series, however, the proportion of children having filled teeth had increased to 70 and 74 percent, respectively.

¹ Includes teeth carious only, those both carious and filled, and those indicated for extraction. ² Based on actual number of teeth carious, filled, or carious and filled. Teeth that are both carious and filled are counted only once. ³ Decayed, missing, and filled. ⁴ Average of the rates for ages 5-16.

Figure 1. Dental caries prevalence in permanent teeth, third treatment series, Woonsocket, R. I., ages 5-16.

Waterman and Knutson (2) point out in a report on a comparable study project in Richmond, Ind., that "continued reduction of the number of teeth indicated for extraction reflects the regularity of complete care during the previous treatment series." This indication of the value of complete and continuing care in saving teeth is supported by the Woonsocket experience. More than 10 times as many permanent teeth per child were indicated for extraction at the start of the first series as in the fourth series (table 3). During the same interval the number of teeth that had been extracted decreased by more than 50 percent. Eleven percent of the children in the fourth series had 1 or more

Figure 2. Dental caries prevalence in permanent teeth, fourth treatment series, Woonsocket, R. I., ages 5-16.

extracted teeth, compared with 22 percent in the first.

Initial examination findings revealed that 47 percent of all primary teeth were carious. In addition, only 4 percent of the children had 1 or more primary teeth which had been filled prior to the first treatment series. Improvement in the status of the primary dentition was observed with each succeeding treatment series. The proportion of decayed primary teeth, for example, decreased to 33 percent in the fourth series, whereas that of children with filled primary teeth increased to 36 percent. For the first three series the average number of carious primary teeth per child was highest in 6-year-

old children, whereas in the four 5-year-old group had the highest (4). At the beginning of the program children averaged 0.99 filled primary teeth per child in the fourth series. However, this figure increased to 3.21 primary teeth per child by the end of the fourth series.

Only children aged 10 years or older in the fourth series could have received treatment in the three preceding rounds. To evaluate the improvement in dental status resulting from regular care, one may compare the rates in the initial and the fourth examination series.

14-year-old children, recognizing at the same time that the group involved in the fourth series also included newly enrolled individuals. At the beginning of the program the average 10-year-old had 5.30 carious, 0.83 filled, and 0.61 missing permanent teeth. In the fourth treatment series, on the other hand, the corresponding averages for children of the same age were 2.06, 1.35, and 0.19. These figures indicate that 10-year-old children in the fourth series had less than half as many carious, five times as many filled, and one-third as many missing permanent teeth as those of similar age in the first series.

Similarly, initial examination of the 14-year-old group showed 10.7 carious, 2.91 filled, and 2.21 missing permanent teeth per child. By contrast, the average 14-year-old in the fourth series had 3.65, 10.66, and 0.79 teeth in the carious, filled and missing categories, respectively. This represented one-third as many decayed, nearly four times as many filled, and one-third as many missing permanent teeth as were observed in children at the start of the program.

¹ Average of the rates for ages 5-16.

number of children on a maintenance basis upon completion of the first treatment series. The practicability of this approach is suggested by the continued decrease in primary teeth indicated for extraction in succeeding treatment series. Each primary tooth filled involved an average of 2 surfaces, compared with 1.5 surfaces for each permanent tooth. This pattern showed little variation throughout the program.

Additional treatment included 754 pulp cappings and 94 vital partial pulpectomies in permanent and primary teeth during the third round. The corresponding numbers for the fourth series were 815 and 86.

Dentist Man-Hours

During the 15 months required to complete the third treatment series, an average of 5.5 dentists were on duty, or a ratio of 1 dentist to 714 children per year. Complete treatment of each child required 1.7 dentist man-hours. An average of 1.9 permanent and 0.6 primary teeth were filled per dentist man-hour in addition to the miscellaneous treatments provided. During the fourth series, 5,004 children were treated by an average of 5.9 dentists, a ratio of 1 dentist to 848 children per year. During this series an average of 1.4 dentist man-hours was required for each completed case. For each dentist man-

hour, an average of 1.6 permanent and 0.7 primary teeth were filled. Table 6 summarizes the ratio of clinic to nonclinic patients; children treated per dentist; dentist man-hours per child; and teeth filled per dentist man-hour during the four series.

The number of teeth filled per dentist man-hour remained essentially constant in all four rounds. The effect of regular, complete dental care in reducing the needs for dental service is indicated by the increased number of children treated annually per dentist and the decrease in

Figure 3. Children treated annually per dentist and dental man-hours per completed case, four treatment series, Woonsocket, R. I., ages 5-16.

Table 6. Selected comparative data for the four treatment series, Woonsocket, R. I., children aged 5-16

Comparative data	Treatment series			
	1	2	3	4

dentist man-hours required to complete each case (fig. 3 and table 6). This continued reduction in need was also reflected in a steady decline in the overall time required to complete succeeding treatment series.

Summary of All Four Series

Over 80 percent of the total enrollment in kindergarten through the ninth grade, or an average of 5,100 school children, received complete dental care in each of the four treatment series of the Woonsocket dental care study. In addition, a small number participated to the extent of receiving partial clinic care. Six percent of the children were cared for regularly by their own dentists, whereas about 10 percent sought no care from any source.

The initial examination disclosed an average of 6.39 carious, 1.32 filled, and 0.99 missing permanent teeth per child for all age groups 5-16 years. During the fourth treatment series the corresponding rates were 2.28, 5.63, and 0.33 teeth per child.

Although care of the primary teeth was selective rather than complete, the filled tooth rate per child for children aged 5-8 years increased from an average of 0.19 teeth in the first series to 2.49 in the final series.

The effect of regular, complete dental treatment in reducing dental needs is indicated by the greater number of children treated annually per dentist, as well as by the decreased dentist

time required to complete each case. Whereas each dentist cared for 384 children during a year in the first series, he was able to extend his services to 848 patients by the fourth round. Only 1.4 dentist man-hours were needed to complete treatment per child in the final series, in contrast to the 3.3 man-hours in the first series. This figure includes the time required to care for the backlog needs of newly enrolled children who had not previously been treated in the program.

The number of months devoted to completing

each of the treatment series was 30, 24, 15, and 12, respectively.

An Important Date

Each month your health department and many hospitals, laboratories, schools, clinics, and homes receive a copy of PUBLIC HEALTH REPORTS, mailed to arrive on the 20th, or even earlier, depending upon geographic location of the subscriber.

Its pages carry timely research reports, analyses of current trends, new methods, concepts, and ideas, and topical reviews for the busy scientist, teacher, or public health worker. Capsule coverage of important public health meetings, like those of the American Public Health Association, help the PHR reader.

Not all our readers receive the journal on the delivery date. An official copy is trickled down to them through a series of other readers. Sometimes the trickle slows to a complete halt.

You can have your personal copy promptly. Use the subscription blank on the inside back cover. Let the 20th of each month be an important date for you, too.

Scheduled for early publication

Venereal Disease in Teen-agers
Ownership of Nursing Homes
The Trachoma Story
Medical Librarianship
A Rural Sanitation Program
Hospital Beds in the United States

research progress report

Germ-Free Amebiasis Studies

This report on progress of germ-free amebiasis research being conducted by the University of Notre Dame and the Public Health Service is based on a paper presented by Bruce P. Phillips at the annual meeting of the American Society of Parasitologists, at Memphis, Tenn., November 4, 1954. Mr. Phillips is a medical protozoologist with the National Microbiological Institute of the Service.

CONVENTIONAL animal experimentation as a key resource in the study of infectious diseases has certain inherent shortcomings. Among them are interference by rival organisms in the animal. An investigator working with a given disease organism in a laboratory animal usually must consider the possible effects of other micro-organisms normally present or accidentally introduced. He must ask if his results are influenced, directly or indirectly, by bacteria normally harbored by the animal, bacteria which in themselves do not ordinarily produce disease.

Germ-Free Animals

To eliminate such uncertain or unpredictable factors is the object of what is known as germ-free medical research. For this work, great pains have been taken to rear and make available for experimental use small laboratory animals—chickens, guinea pigs, or mice—which are free of the bacteria harbored by conventional or “contaminated” animals.

Scientists first attempted to rear germ-free animals—chickens—in 1897. Contamination occurred within the first few days. The investigators concluded that it is practically impos-

sible to free the egg surface from bacteria, and that chickens are therefore unsuitable for germ-free studies. Nevertheless, another scientist, Schottelius, persevered. After 9 years, he reported, he raised about 30 germ-free birds; some remained germ-free for as long as 30 days. But his germ-free birds sickened and died, whereas others which he deliberately contaminated after a short period developed normally. He concluded that intestinal bacteria are indispensable to the nutrition of vertebrates.

Soon after, these conclusions were refuted. Cohendy in 1912 reported rearing 17 healthy germ-free chickens for as long as 40 days.

After a lapse of nearly 25 years, Balzam in 1937 reported he had reared 5 healthy chickens for 59 days, germ-free, for an experiment with nutrition. He concluded that intestinal bacteria had no appreciable influence on the digestibility of food in the chicken.

Chickens have proved particularly appropriate for germ-free breeding. The chick feeds itself from birth. It needs fewer caretakers than the mammals. Advanced knowledge of its genetic and embryonic history is also an advantage to research.

The first long-term program to rear germ-free animals began in 1928 at the University of

Notre Dame. This attempt to resolve the many complex problems of creating and maintaining a sterile environment for germ-free animals drew on resources of mechanics, engineering, physics, chemistry, and biology. The bacteriological triumph gave rise to a specialty known as biological engineering, which designed the instruments and apparatus of the project. Only by these applied skills was it possible to put germ-free animal breeding on a practical basis. Trained technicians were enabled by ingenious equipment to relieve highly trained research personnel of the routine feeding and management of the animals.

The objective at Notre Dame was to introduce an animal, germ-free at birth, into a sterile environment, and to maintain it and its progeny germ-free. The feat required that the animal be isolated from germs in its living quarters, its air, its food, and all its other contacts.

Early attempts to achieve this end depended on a series of steps, each using germ-free apparatus with aseptic technique. Since any one step was a weak link in the chain, Notre Dame devised a system of total control. The entire apparatus for moving the animals, cleaning cages, and handling food is sterilized at one time under steam pressure.

This achievement at Notre Dame, under the leadership of Dr. James A. Reyniers, has been followed with deep interest by scientists in many research institutions. At the National Institutes of Health of the Public Health Service, the availability of germ-free animals led to the initiation of a study 2 years ago by the National Microbiological Institute's Laboratory of Tropical Diseases, in cooperation with the University of Notre Dame.

Amebiasis Study

The problem selected for study at the National Institutes of Health was a widespread intestinal infection known as amebiasis. Many will remember the serious outbreak of this disease in Chicago during the World's Fair 20 years ago. Amebic infection is common in the United States. It is found in an estimated 7 percent of our population.

Amebic dysentery has long been viewed as a clinical anomaly, in that it presents an unusually

wide and varied range of manifestations. To explain these variations, studies were devised to investigate the agent of this disease and its capacity to produce infection. Among them have been studies to determine the effects of inoculation of germ-free animals with amebas which are themselves free of bacterial contamination.

Germ-Free Amebas

These studies were proposed because the initial attack of this disease agent usually occurs in the lower intestinal tract, where it lives with a large number of species of bacteria. It had never been possible for the ameba to be grown in the test tube without the presence of bacteria until a scientist in the National Microbiological Institute succeeded in cultivating the ameba in bacteria-free cultures of a South American trypanosome.

Two groups of animals were used for inoculation with the germ-free ameba: germ-free guinea pigs and conventional guinea pigs. Both groups were maintained on identical sterilized rations.

None of the 35 germ-free animals developed amebic lesions before they were sacrificed on the 33d day. Of the 37 conventional animals inoculated as controls, 34 developed ulcerative amebic disease, and the remaining 3 were shown to harbor the infecting agent when sacrificed on the 21st day.

In contrast to these results, 2 series of pre-experimental germ-free animals were fed by mouth single species of common intestinal bacteria before being inoculated with bacteria-free ameba. All of these animals developed acute amebic diseases with typical lesions.

Bacterial Effect

These results offered first concrete evidence that bacteria have a role in the experimental production of disease by the ameba. In relation to amebic disease in humans, the evidence suggests a possible explanation for the disparities frequently noted in clinical manifestations and in effects of treatment of amebic dysentery.

This study, made possible by the use of Notre Dame's germ-free animals and facilities, repre-

sented an expenditure by the National Institutes of Health of only \$21,000.

The National Microbiological Institute, the National Institute of Arthritis and Metabolic Diseases, and the National Institute of Dental Research have plans for additional germ-free studies.

At the Microbiological Institute, new knowledge is sought about the multitude of infecting agents that assault the tissues of man. Germ-free studies aid in this task, for they supply a method and a freedom from bacterial interference heretofore lacking.

Germ-free animals may be useful in investigating the site of multiplication of the poliomyelitis virus in the intestinal tract and the influence on its multiplication and excretion.

Another project would study resistance of germ-free animals to infection with such agents as staphylococci. This is of interest to clinical medicine because staphylococci, once they become resistant to antibiotic drugs, may cause severe complicating secondary infections.

Other studies may determine whether certain fungi and yeasts become pathogenic, or disease producing, if the effect of bacterial growth in the respiratory and gastrointestinal tracts is eliminated.

The hope is that germ-free techniques have reached the stage where they can be applied to the study of a wide variety of complex biological problems, as evidenced 70 years ago by Pasteur.

New Juvenile Delinquency Division in Children's Bureau

With the establishment of a Division of Juvenile Delinquency, the Children's Bureau of the Department of Health, Education, and Welfare will increase its services to public and private agencies and to organizations concerned with the nationwide problem of juvenile delinquency. The new division will work closely with existing programs of the Children's Bureau to extend and improve its health and welfare services for physically, socially, and emotionally handicapped children.

Philip Gordon Green, former chief juvenile probation officer of the Juvenile Court of San Francisco, will direct the division. Associated with him will be William H. Sheridan as chief of the Technical Aid Branch, Mrs. Elliot Turner Studt as chief of the Training Branch, and Donald George Blackburn as consultant on institutions for delinquent youth. Specialists on juvenile police, courts and probation services, and community services are to be appointed.

The Children's Bureau is also expanding its study program and statistical reporting on children who come to the attention of the courts.

Roof Rats in Southwest Georgia

Two rodent species of the genus *Rattus* (*R. norvegicus* and *R. rattus*) have played important roles in the transmission of some of the earth's most serious diseases. The control of these rodents and of their ectoparasites has proved an effective means of combating these diseases. However, efficient control of rodents and/or their ectoparasites requires a thorough understanding of the animal's life history and habits.

Many good studies have contributed to a sound understanding of Norway rat populations, but the works are few which analyze the population dynamics of roof rats. The Georgia studies made efforts to increase understanding of the phenomena of the habits and population of roof rats. It is hoped that the reported findings will lead to more efficient control of roof rats and to a greater reduction in the diseases transmitted by this species.

The objectives of the study were (1) to determine the basic population units and the factors responsible for their well-being, (2) to develop methods for observing and detecting changes in density of rat populations, (3) to analyze mortality rates from catch-mark-release data, (4) to determine movement rates and distances traveled, and (5) to learn the extent to which rats maintain a feral existence.

The study was conducted in Brooks, Thomas, and Grady counties, Ga., from June 1951 through January 1953. Rats were live-trapped, marked, and released in five rural study areas. Trapping and marking methods are described. Some additional data were gathered from the steel trapping records of murine typhus surveillance programs.

Typical habitat and basic living requirements are described. Population changes are analyzed by comparison of trap-catch rates, by change in colony distribution, by farmer and

trapper recollection, and by changes in age distribution. All methods of analysis point in the direction of a reduced rat population between 1947 and 1953.

Public Health

MONOGRAPH

No. 27

The accompanying summary covers the principal findings presented in Public Health Monograph No. 27, published concurrently with this issue of Public Health Reports. The author, formerly a wildlife research biologist with the Public Health Service Communicable Disease Center, is a public health biologist with the Santa Clara County (Calif.) Health Department.

Readers wishing the data in full may purchase copies of the monograph from the Superintendent of Documents, United States Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of the major universities and in selected public libraries.

. . .

Ecke, Dean H.: Roof rat populations in southwest Georgia. Public Health Monograph No. 27 (Public Health Service Publication No. 373). 20 pages. Illustrations. U. S. Government Printing Office, Washington, D. C., 1955. Price 20 cents.

Mortality rates computed from retrapping data show that females live longer than males, and that over 95 percent of any given population could be expected to die within 12 months. A distinction is made between "disappearance rates" as directly observed in trapping records and "true mortality" rates. It is also shown that males attain greater size than females.

Rat movement was found to be quite restricted. Of 546 rats retrapped, only 4 were taken at distances greater than 500 yards from

their original capture site. Twelve percent of captured rats moved between buildings at distances under 300 yards, and individual moves over 100 yards were rare.

No evidence could be found to substantiate local beliefs that rats migrated between fields and farm buildings during seasonal changes. Data from field trapping, absence of rat sign in fields, and stomach analyses of foxes combine to discount any appreciable population of feral rats in the vicinity of study.

The Rainy River Basin

Public Health Service Publication No. 380 (Water Pollution Series No. 68). 1954. 6 pages; map and tables.

The Minnesota River Basin and the Rainy River Basin pollution control programs are summarized in these two publications of the water pollution control series.

The Minnesota River Basin consists of a watershed area of about 16,920 square miles, located in southwestern Minnesota, South Dakota, and Iowa. The principal tributaries are the Little Minnesota, Chippewa, Cottonwood, Redwood, Lac Qui Parle, Pomme de Terre, and Yellow Medicine Rivers. To protect the water of the basin against pollution, the report recommends construction of 64 new or enlarged municipal sewage treatment plants to serve about 100,000 people, plus new or improved waste treatment facilities at 19 industrial plants.

The water pollution control program for the Minnesota River Basin has been developed jointly by the water pollution control agencies of Iowa, Minnesota, and South Dakota with the cooperation of Federal water pollution agencies.

The Rainy River Basin lies in Ontario and in the north central part of Minnesota. The river forms a portion of the boundary between Canada and Minnesota and drains an area of approximately 21,000 square miles, 11,300 of which are in Minnesota.

The water pollution control program for the portion of the Rainy River Basin within the United States has been developed and put into operation by the Water Pollution Control Agency of Minnesota, which had the cooperation of other authorities during the planning period.

Health Manpower Source Book

Medical Record Librarians

Public Health Service Publication No. 263. Section 6, 1954. By Maryland Y. Pennell, Marion E. Altenderfer, and Olive G. Johnson. 43 pages; tables. 30 cents.

This sixth section of the health manpower source book series pre-

sents data on the number, characteristics, and distribution of medical record librarians. A survey by the American Association of Medical Record Librarians in 1953 gave information on employment status and educational background. Additional material was obtained from the association files and from the approved schools for the training of medical record librarians.

About 13 percent of the active medical record librarians have been graduated from approved schools for training in that field. In 1953-54, the 24 approved schools had a student capacity of 219 and an enrollment of 114. Of the 1,152 persons graduated from accredited schools during the period 1928-53, almost half are currently active in their profession.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

The twin problem of encouraging foreign trade while protecting the health of the Nation . . . Shellfish, in the shellfish sanitation control program of the Public Health Service, are defined as "fresh or frozen oysters, clams, and mussels."

Shellfish Importation into the United States

By RICHARD S. GREEN, M.S.

IMPORTATION of shellfish presents several complex sanitation problems to health and food control officials, as well as to industry. The program of shellfish sanitation control of the Public Health Service is based on the endorsement of State operations. The listing of certified dealers in a periodic compilation, designed for use in consumer areas, is the backbone of this voluntary system of control. Since 1948, Canada and the United States have operated under an agreement to use this technique for shellfish shipped across the border.

The acceptance of this concept of the certification system and an understanding of the health department surveillance involved in it brought about demands for similar attention to the growing volume of shipments of shellfish from other countries. Since many health services in the United States require that oysters, clams, and mussels be purchased from certified

dealers, shipments from foreign countries other than Canada have found a restricted market, even though they have been admitted legally to the country under the terms of the Federal Food, Drug, and Cosmetic Act (1). The Food and Drug Administration is responsible for permitting or denying entry to food imports under that act.

Representatives of foreign countries and United States importers have asked the Public Health Service how their shellfish can be accepted in a manner similar to domestic and Canadian shellfish. At the same time, State and local health departments have asked the Service what they should do about foreign shellfish which have appeared on the market. The Public Health Service, although it has guided the domestic control program for many years, has no legal jurisdiction in this issue. Since the shellfish sanitation program was developed, and still functions, through cooperation among the States, industry, and the Public Health Service, major adjustments in the program must be worked out by agreement among these interested parties.

As indicated above, responsibility for permitting or denying entry of shellfish shipments when presented at ports of entry, under the terms of the Food, Drug, and Cosmetic Act, lies with the Food and Drug Administration, a companion agency of the Public Health Service in the Department of Health, Education, and

Mr. Green, chief of the Shellfish Branch from July 1947 to November 1954, is now chief of the Facilities Protection Project, Water Supply and Water Pollution Control Program, Division of Sanitary Engineering Services, Public Health Service. This paper is based on comments presented at the Joint Convention of the Oyster Institute of North America and the National Shellfisheries Association, Boston, August 4, 1954.

Welfare. Whenever the Food and Drug Administration finds, from the examination of samples, or otherwise, that such shipments of shellfish are insanitary, adulterated, or misbranded, their entry is refused. In the absence of such evidence, entry must be permitted.

The Concept of Control at Source

It is generally agreed that, in the instance of oysters, clams, and mussels, protection of the consumer is best assured by sanitary controls over conditions attending the growing, harvesting, packing, and shipping of the shellfish. This principle of "control at source" has governed the cooperative domestic shellfish program of the Public Health Service, the States, and industry. It is employed also in the agreement with Canada. Its value may be judged by the low incidence of shellfish-borne enteric disease, despite the more than 400 polluted areas on our coastlines that are legally closed to shellfish harvesting.

Objective examination of samples collected from foreign shellfish shipments on their arrival at an American port does not always give satisfactory evidence as to the conditions under which the shellfish were produced and packed. It is, therefore, difficult to decide which shipments should be admitted and which denied entry, particularly when bacteriological findings do not show presence of significantly large numbers of coliform organisms, and when other objective findings are satisfactory.

Prior to World War II, few shipments of shellfish came into the United States except from Canada and Mexico. Most of the shipments from Mexico were pismo clams (*Tivela stultorum*), although an occasional shipment of shucked oysters was offered for entry. In 1952 somewhat over a half million pounds of clam meats were imported from Mexico, principally through the San Diego and Los Angeles ports of entry. In 1953 this figure was close to three-fourths of a million pounds. It is believed that almost all of these clams are used in production of heat-processed clam chowder; since no apparent attempt has been made to distribute unprocessed clams beyond the State of entry, the question of certification of clam producers in Mexico has not arisen.

With expansion of the frozen food industry since the end of World War II, several other foreign countries have developed an interest in the United States market for bivalve shellfish, principally frozen clams. Japan, Iceland, Australia, The Netherlands, France, Spain, China, and Panama have all exported or indicated an interest in exporting frozen clams, mussels, or oysters to the United States. The total volume of shellfish shipped here has been relatively small, somewhere in the neighborhood of 1 or 2 percent of domestic production. However, foreign shellfish, except those produced in Canada, have been faced with the restrictions resulting from lack of certification. It is uncertain what the ultimate volume of shellfish imports might be if such restrictions were overcome.

The Case for International Trade

Although it is outside the usual field of public health to dwell on such facts as dollar exchange value, tariffs, and the importance to these foreign governments of trade with the United States, these factors bear directly on the regulatory problem. Specialists in such matters have analyzed the situation about as follows:

International trade in frozen shellfish, thanks to technical advances, is now possible on a worldwide basis. Producers of shellfish in distant countries are eager to help to satisfy what appears to be an expanded demand for shellfish in the United States. The interest of foreign governments stems from the importance of trade to their national economies and the importance that all free world countries attach to close ties with the United States. It is held to be in our interest to foster such ties and to enable friendly countries to gain strength through trade. Their welfare and ours are said to require that they be able to earn dollars from their exports to the United States in order to buy the products of our farms and factories.

Japan and Iceland, in particular, must sell the United States more goods than they now do to pay for American products they need and want. Iceland has virtually nothing except marine products to sell abroad, and marine products are among the few commodities which

Japan can produce without the use of imported raw materials.

In the last few years, the Governments of Iceland, Japan, The Netherlands, and Australia have made known to the Department of State and to the Public Health Service their interest in working out some arrangements which would remove unnecessary restrictions against the marketing of imported shellfish without endangering public health. As the Department of State has asserted America's interest in this problem, the Public Health Service has examined available facts with respect to the issue of expanding the present system of certification to these and other foreign countries.

The Public Health Service does not want its cooperative system of shellfish sanitation control within the United States to act as an artificial trade barrier against legitimate shellfish shipments which have been produced and packed under conditions equal to those required of American packers. On the other hand, even if the Public Health Service had the authority to do so—which it does not—there are difficulties in extending this certification system to other countries. Full knowledge of these difficulties is necessary in order to deal with the problem intelligently.

The Complexity of Foreign Control

Public Health Service endorsement of State shellfish sanitation programs presumes that representatives of the Service keep in close touch with control measures of the individual producing States by reasonably frequent consultations with State personnel, cooperative investigations, and check inspections. Without this kind of contact, the Public Health Service could not report adequately to the country as a whole on the effectiveness of the local procedures. The agreement with Canada specifically includes provisions for the exchange of information on methods of production and handling of shellfish, and for inspection visits across the border.

From a practical point of view, it has been easy for the Public Health Service to meet these provisions of the agreement with Canada. The capitals of the two countries are only a few hours apart by air, and long distance telephone conversations are relatively inexpensive.

It costs the United States Government a very small sum each year to keep in close touch with operations in the Canadian Maritime Provinces of eastern Canada and in British Columbia, by extending routine field trips to those areas while Public Health Service inspectors are working in the State of Maine or the State of Washington. Health officials in the two countries have many mutual concerns; thus, official business easily includes shellfish sanitation along with other topics, and a constant interchange of information is possible at relatively low cost. In addition, cooperative efforts with Canada have been built on a long history of parallel development in the two countries, both as to technical procedures and administrative operations.

There are no provisions in the Food, Drug, and Cosmetic Act which would make possible routine international exchange of information about techniques of sanitation control at source. There is no provision for setting up any plan of international certification or endorsement of any foreign control program. In the view of officials of the Food and Drug Administration, the only justification under the Food, Drug, and Cosmetic Act for that Administration to use its appropriated funds to send a representative to a foreign country would be to gain information considered necessary for the proper enforcement of the act in connection with foods or drugs offered for entry into the United States.

Such visits have been rare for various reasons. In the first place, a single trip to a foreign country for inspection purposes can develop information of only limited usefulness. In order to carry out the type of inspections performed in this country under authority of the Federal Food, Drug, and Cosmetic Act, it is sometimes necessary to visit one or more plants several times during the year. Because of limitations of funds and personnel, such trips to foreign countries have limited value for control purposes. Compared with the expenditure on inspections in this country, they are also uneconomic, although occasions may arise when a single trip or visit to a foreign country may supply basic information necessary to evaluate a particular situation.

Aside from the complicated administrative problems, certain other factors are important.

There are limitations to the objective ex-

amination of shellfish at the time of arrival of shipments in this country. If strongly positive bacteriological results are obtained, one may assume that the shellfish were produced or handled under insanitary conditions. However, when bacteriological results are negative, interpretation becomes much more difficult.

In spite of a great deal of research, there has not been established for even our own species of shellfish any firm relationship between bacterial content of shucked shellfish in the market and the quality of growing areas and conditions of handling. This is why it is not yet possible to adopt a final bacteriological standard for market quality. Work which has been done so far in this field has dealt chiefly with fresh shucked oysters and clams and has not considered frozen products. Undoubtedly, the freezing and prolonged storage of shellfish produced abroad will have some effect on their apparent bacterial content.

In the United States and Canada, certain species of shellfish, notably clams and mussels, are sometimes subject to the accumulation of organic toxins. The origin and action of these toxins are fairly well understood, and a complex administrative control program is in operation to prevent toxic shellfish from being used commercially. Adequate test procedures are available and are being improved. However, there is some reason to believe that toxin which sometimes affects certain species of foreign shellfish may not be so well understood, and it is not certain that adequate tests have been developed.

Most of the frozen shellfish which would be shipped to the United States would be cooked before use. In fact, one importer has been investigating the feasibility of introduc-

ing clams which would be given some cooking before being frozen for shipment, this product being intended for use as chowder stock. It is unlikely that many frozen shellfish from abroad would be consumed raw. This factor is mentioned, not because there should be any significantly different standards applied to shellfish intended to be heat processed before sale but simply because the facts seem to indicate that any health hazard which might be present in connection with bacterial contamination of frozen shellfish from abroad would be considerably reduced by cooking. However, this expected heat treatment should not be employed in any way as a coverup for a filthy item. The Food and Drug Administration and the Public Health Service both hold this position.

There are in operation two parallel mechanisms of sanitary control for imported shellfish. One admits shellfish to this country, and, at the same time, the other restricts their market. Foreign governments find it difficult to understand that two different sources of legal authority in the United States, one Federal and one State, govern the importation and the marketing, respectively.

After a free exchange of views at the National Conference on Shellfish Sanitation, September 9 and 10, 1954, industry and government representatives agreed that recommendations on the significance of traffic in imported shellfish should come from the State Department. The State Department continues to study the developing trends of this commerce.

Shellfish Poisoning Episode In False Pass, Alaska

By H. F. MEYERS, B.S.,
and D. K. HILLIARD, M.S.

A FATAL CASE of shellfish poisoning attributed to eating mussels that had fed on the dinoflagellate plankton, *Gonyaulax catenella*, was reported July 21, 1954, by the United States Commissioner at Dutch Harbor, Alaska. Since a survey of shellfish toxicity was being conducted in northern Alaskan waters at the time by the Public Health Service Arctic Health Research Center in Anchorage, the case was investigated thoroughly.

The poisoning occurred at a salmon cannery in False Pass on the northeastern end of Unimak Island in the Aleutian Chain. The following is an excerpt from the log of Dr. J. Clark, Alderwood Manor, Wash., physician at the cannery hospital, who gave invaluable assistance and cooperation at False Pass:

"Patient seen by physician at 4:45 p. m. and found suffering severe abdominal pain and nausea with vomiting. Man expired at 5:00 p. m. same date. Time of onset of illness between 2:00 p. m. and 4:45 p. m. All information gathered from fellow workers as man was unable to talk to physician. It is stated he was quite ill before calling for assistance. Symptoms when seen were those of poisoning and believed to have been caused by mussels."

Four days prior to the fatality, six other cannery workers consumed mussels from the same source. They reported to the hospital, however, at the first signs of illness, received gastric lavage and medications, and were released the next day.

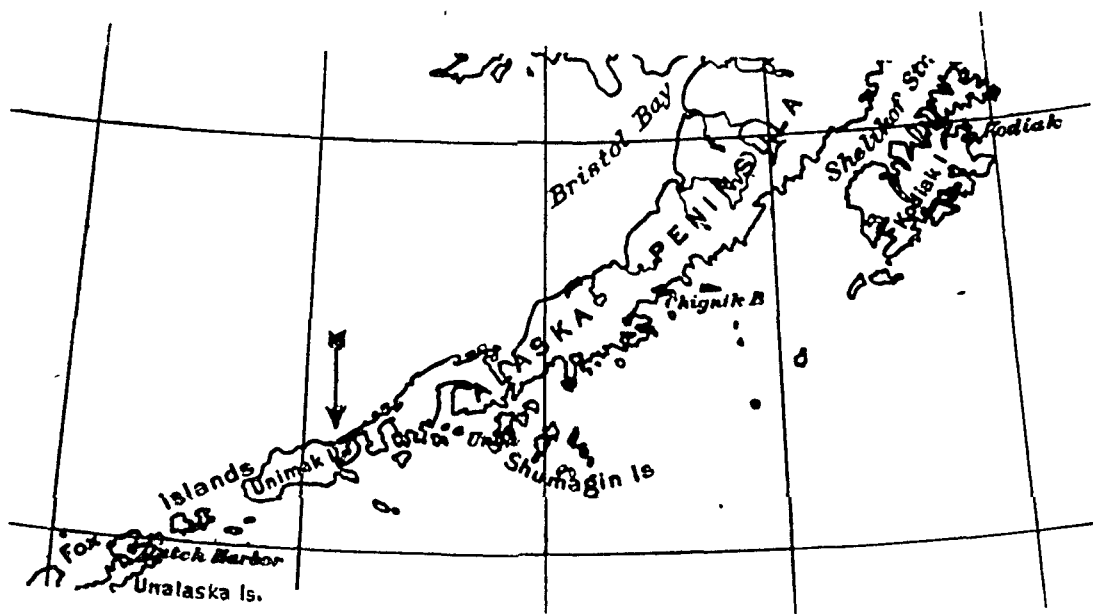

Mr. Meyers, a chemist, and Mr. Hilliard, an aquatic biologist, are with the Public Health Service Arctic Health Research Center at Anchorage, Alaska.

The beaches at False Pass are primarily rock with some sand and gravel. The shoreline is irregular and has small coves which are undisturbed by the main current. These small coves are rich in various forms of algae and zooplankton, in addition to the usual debris and cannery waste. While the maximum difference between high and low tide is very small (2 feet) the current is extremely swift, changing direction with each change of tide. According to cannery workers, the current usually attains a velocity of from 5 to 7 knots.

Specimens of *Mytilus edulis* Linnaeus, the shellfish eaten by the cannery workers, were collected from several locations along the beach. While great numbers of the mussels were attached in clusters to rocks exposed at low tide, an even greater number were attached to the ocean floor and obviously not exposed during extreme tides. The mussels were extracted at the local cannery hospital, bottled, and retained for bioassay at the Arctic Health Research Center laboratory. Plankton samples were collected simultaneously and preserved in Transeau's solution for laboratory examination.

The extraction and bioassay were carried out according to currently accepted methods, that is, 100 gm. of mussel tissue were ground and mixed with 100 ml. of 0.1N hydrochloric acid. The mixture was refluxed for 5 minutes, rather than boiled in a beaker, so that it was unnecessary to bring the mixture back to the original volume. The pH was adjusted to 4.0-4.5, the mixture centrifuged, and the clear supernatant liquid withdrawn and preserved in sterile bottles. One ml. of this liquid, when injected intraperitoneally into a 19.8 gm. mouse, caused death in 48 seconds. Numerous dilutions were made, and a range of from 74,000 to 106,000 mouse units per 100 gm. of raw material was obtained. A mouse unit is the amount of poison contained in 1 ml., pH 4.0-4.5, that will kill a 20-gm. mouse in 15-20 minutes after intraperitoneal inoculation. It has been estimated by other workers that the minimum lethal dose for man is probably between 20,000 and 40,000 mouse units (1). On the basis of this evidence

False Pass (arrow) latitude $54^{\circ}52'$ N., longitude $163^{\circ}24'$ W., is the first break in the Alaska Peninsula allowing waters from the Bering Sea to come in contact with the Pacific Ocean.

the Arctic Health Research Center stated, for public information, that less than 4 ounces of raw material would produce lethal results.

Microscopic examination of the plankton samples obtained at False Pass indicated that the organism *Gonyaulax catenella* Whedon and Kofojd was present, but not in large numbers. Since travel in the Aleutian Chain is almost entirely by air and is dependent upon weather and fog conditions, 2 weeks had elapsed between the death reported and collection of samples. It is possible that the ideal conditions for growth of this organism no longer existed. It has been stated (2) that "The strong radiation of the sun together with the cold nutrient waters due to upwellings seem to be ideal for the growth of this dinoflagellate." The nutrition supplied by the cannery waste together with the cold waters of the Bering Sea coming in contact with the warm

waters of the Pacific in this small pass would more than fulfill these ideal conditions.

Future work is planned in connection with shellfish poisoning in the Aleutian Chain, particularly in the Kodiak area. Natives at False Pass, Kodiak, and at other points on the Aleutian Chain refer to individuals who in the past have become violently ill, with an occasional death, after eating shellfish. Since there was seldom a physician available, the stories could not be substantiated.

The American Social Hygiene Association

By C. WALTER CLARKE, M.D.

TODAY, 40 years after the American Federation for Sex Hygiene and the American Vigilance Association merged to form the American Social Hygiene Association, the country recognizes that, although much has been accomplished in sex education, venereal disease control, and the suppression of prostitution, the problems the American Social Hygiene Association faced up to originally remain a challenge. Nor is it so remarkable that present social hygiene problems are in many ways identical to those of 1914. Problems rooted in human nature require generations of cooperative planning, research, demonstration, and field work for their solution. They do not lend themselves to the once-over-lightly treatment optimists would give. Instead, as one or another aspect of these problems has changed according to time or circumstances, emphases have changed to meet the need.

Mobilizing Public Opinion

Dr. Charles W. Eliot, John D. Rockefeller, Jr., James Bronson Reynolds, Dr. William F. Snow, and others present at the first meeting

Dr. Clarke, executive director emeritus of the American Social Hygiene Association, has been a member of the association's staff since 1914 as field secretary, European representative, medical director, and executive director. He has served as clinical professor of public health practice, Harvard University, and has been associated with a number of State, national, and international health and welfare organizations. During World War II, Dr. Clarke was consultant to the Secretary of War.

of the new national association in 1914 did not minimize the difficulties before them. They knew there was as yet no public opinion to support their aims and that the channels through which public opinion can usually be molded were firmly closed to them. Public discussion of sex problems was taboo. On the credit side, however, they had the support of distinguished leaders who could eventually influence public opinion. Men and women like David Starr Jordan, Jane Addams, Grace Dodge, Cardinal Gibbons, Felix Warburg, and Julius Rosenwald had been attracted to the social hygiene movement by the work of the association's two parent organizations and especially by the work of Dr. Prince A. Morrow, president and founder of the American Federation for Sex Hygiene. Perhaps less effective was the support of the 12 "sex hygiene societies" and about an equal number of "vice commissions" in cities from coast to coast. Their feeble, fumbling attacks on the great problems of sex ignorance, sexual vice, and venereal disease did little to break down ignorance and complacency.

As it was, only a few individuals had the courage to participate in this unpopular movement. The earliest leaders were preponderantly physicians, whose professional training permitted them to discuss social hygiene without censure, and a few clergymen, businessmen, and educators. The new association set out to increase the number of such leaders, people who could influence public opinion and open channels to the public. Once the conspiracy of silence in the press, pulpit, classroom, and home was overcome, the American Social Hygiene Association could make progress in its efforts to help correct abominable conditions.

Although World War I was responsible for

lence, made censuses of venereal disease cases under private and clinic treatment, evaluated the venereal disease control programs of cities and counties and suggested improvements, drafted and successfully urged the adoption of the first prenatal examination law and an improved premarital examination law, and published digests of laws dealing with the venereal diseases, prostitution, and related offenses. Through the League of Nations, League of Red Cross Societies, and International Union Against the Venereal Diseases, the association aided international health and social welfare programs, especially those aimed at suppressing traffic for immoral purposes in women and children. From 1935 to 1938 an officer of the ASHA organized a venereal disease control program for New York City, one of the most complete at that time.

A joint committee of the American Pharmaceutical Association and the ASHA, formed in 1939, has stimulated cooperation between the two groups in informing the public about the dangers of quacks and nostrums and in stressing the fact that only members of the medical profession can give adequate treatment for venereal diseases.

In 1920 ASHA began to build public opinion toward a new national effort. This was a long process. Not until 1937 was the time ripe to ask Congress for new Federal legislation based on recommendations of the Conference of State and Provincial Health Authorities, American Social Hygiene Association, and other agencies, after careful studies by the Public Health Service and State health authorities. The LaFollette-Bulwinkle bill, passed in 1938 without opposition, authorized the appropriation of \$3 million to start venereal disease control operations. As the program developed, appropriations were increased. With the Federal Government at the helm of the control program, it was not long before State and Territorial health departments were using new and highly effective control techniques in an integrated attack against venereal disease. The importance of Federal leadership was proved at this time. By the time the United States entered World War II, medical and health authorities were reasonably well provided with facilities

and personnel to cope with an anticipated rise in incidence of syphilis and gonorrhea resulting from disturbed social conditions during and following the war.

World War II

In September 1939, when President Roosevelt declared a "limited emergency" the American Social Hygiene Association immediately turned all its resources to activities in support of the defense effort. In 1940 the War and Navy Departments pledged in an 8-point agreement to control venereal disease near concentrations of the armed forces or defense workers, and they agreed to cooperate with police authorities in repressing prostitution. The American Social Hygiene Association and State and local social hygiene groups set out to stimulate public support.

After mobilization began, on the basis of the association's suggested legislation, Congress passed the May Act, which gave the Army and Navy authority to cope with prostitution conditions near training centers. At the association's suggestion, the Federal Security Agency created the Social Protection Division to cooperate with State and local officials in maintaining a wholesome environment near training centers, and the Federal Security Administrator established an Interdepartmental Venereal Disease Committee to facilitate cooperation between the Federal Security Agency and the Army, Navy, and American Social Hygiene Association.

As a member of a team seeking to protect the armed forces from prostitution and venereal disease, the association provided up-to-date facts about prostitution conditions near military installations; encouraged civilian support of the official health and welfare program for protecting the armed forces and defense workers; participated in training personnel for venereal disease control activities; and helped provide the Army and Navy with educational materials. An officer of the association served as consultant on venereal disease control to the Secretary of War and as a member of the National Research Council's committee supervising experiments in penicillin therapy for syphilis and gonorrhea.

Existence of prostitution in representative cities in the United States and Territories, 1948-53.

As a result of all these official and voluntary activities, the venereal diseases were kept under control to a greater extent than during any other war in our history (3).

Character guidance and education programs in the armed forces, plus widespread cooperation among government, military, and community agencies, also had a beneficial effect in decreasing prostitution. In 1942 the association's survey of prostitution showed an improvement in conditions. Civilians in communities which had long tolerated prostitution had had to reverse their thinking when the May Act declared prostitution a menace to the health and welfare of service personnel. More and more, people came to regard it as a social evil that weakened all law enforcement, exploited young people, and endangered the health and welfare of all. In its efforts to keep communities wholesome, the association had the support of such agencies as the Federal Bureau of Investigation; American Bar Association, which appointed a Committee on Courts and Social Protection to help control vice; National Police Committee on Social Protection, which developed new techniques of law enforcement in repressing prostitution; National Sheriffs' Association and International Association of Police Chiefs, which adopted resolutions condemning toleration of prostitution; General Federation of Women's Clubs; and Federal Council of Churches.

In 1944 with the establishment of Joint Army-Navy Disciplinary Control Boards (which now encompass all the services), ASHA and other interested civilian groups sent their

representatives to board meetings as advisers requested by the military. ASHA's special contribution was to advise on civilian education and repression of prostitution and to supply the facts on prostitution conditions near military establishments.

Postwar Period

In 1946 and 1947 venereal disease rates at first rose to a high point and then began to fall as penicillin became more widely used, as vigorous venereal disease case finding and contact tracing and activities repressing prostitution were instituted, and as social conditions became more stable. After the discontinuance of the Federal Social Protection Division, the association reestablished its Washington liaison office and its field offices across the country. (This expansion was financed by the United Service Organizations and later by the United Defense Fund.) When mobilization began in 1948, the military asked ASHA to pay special attention to communities near military camps in surveying prostitution conditions. The association also responded to requests for millions of pamphlets warning young servicemen about the dangers of venereal disease and other menaces to their health or morale. These services the association is still providing.

Like other interested organizations, the American Social Hygiene Association has considerable appreciation of the great accomplishments in venereal disease control during the last several years. ASHA is encouraged about the prospects of ultimate control of these dis-

Over 7 million women have seen the film in the past 4½ years, four times as many people as have seen any other health film, and, in what seems to be an upswing of interest during the last year and a half, 1½ million women saw it in 1953. The total influence upon these people and upon others with whom they may associate, of course, can never be calculated. In the certainty that Breast Self-Examination can profoundly effect efforts toward the successful control of breast cancer, this educational material will continue to be offered to the women of this and other countries.

Helicopter Ambulance Service

BUFFALO, N. Y. Kenmore Mercy Hospital in Kenmore, N. Y., a suburb of Buffalo, is one of the two hospitals in the United States that now has helicopter emergency ambulance service. A temporary heliport, a 20-foot square wooden platform, has been constructed a few feet from the emergency entrance to the hospital, and a helicopter is on call any time of the day or night.

The service was instituted last fall with an offer by the Bell Aircraft Corporation to make available one of its helicopters for use in rushing critically sick or injured patients to the hospital. Physicians in this highly industrialized area of approximately a million people estimate that the helicopter will be used for at least 8 to 10 patients annually—perhaps a stricken sailor aboard a lake freighter miles from port, or an expectant mother in a remote, snowbound farmhouse, or a wounded hunter along a wooded trail.

A call to the hospital or the corporation for the service is immediately referred to the company physician, who dispatches the helicopter if conditions warrant its use. All the company's medical personnel

A trial run with an "accident victim" officially opened the new heliport at Kenmore Mercy Hospital. Note that even before the helicopter's rotor blade stopped turning, the top was lifted from the helicopter litter.

and guards have been given instruction on the handling of litters.

Used extensively during the Korean conflict to evacuate injured fighting men and civilians, the helicopter has proved its usefulness in removing injured persons from areas inaccessible to other forms of vehicular transportation. During floods in Holland, avalanches in the Alps, and earthquakes in the Ionian Islands off the coast of Greece, rotorcraft performed formidable rescue feats.

Helicopter ambulance service was first established in the United States

at a hospital in Santa Monica, Calif. Here a rooftop platform serves as a landing area, and helicopters are made available by rotorcraft firms in the Los Angeles area. Arrangements are now being made for the construction of a heliport in the Dallas-Fort Worth area.

It is not practical from an expense standpoint for a hospital to maintain and operate a helicopter. It might be practical, however, for local governments to own rotorcraft since they could be used to augment the services of a number of municipal agencies.

State Air Pollution Control Activities

By RICHARD L. WOODWARD, Ph.D.

AIR POLLUTION CONTROL in the United States has traditionally been a function of municipal governments. Virtually all of our larger cities have some type of ordinance for controlling air pollution. In the past, most of these laws were directed primarily at controlling coal smoke, but in recent years many of the laws have been broadened to consider other air pollutants as well. Most of the recently adopted air pollution control ordinances contain provisions on gas, vapor, fumes, and dusts from sources other than coal combustion.

With the growth of metropolitan areas and the movement of industries to suburban sites, it has become apparent that a municipality frequently is an unsuitable unit for operating an effective air pollution control program. If city A is carrying on a vigorous program of air pollution control, while neighboring city B does little or nothing, not only does the pollution from B affect A when the wind is in the right direction, but the residents and industries in city A will resist enforcement of their own

laws. To overcome this difficulty, government units which control larger areas have been utilized. The first of these was in the Boston metropolitan area. The area, including some 31 cities and towns, has had a smoke control program since 1910 under the supervision of the division of smoke inspection, Massachusetts Department of Public Utilities.

In other areas the county was chosen as a suitable administrative unit. Hudson County, N. J., adopted a smoke control ordinance in 1931. In 1947 California passed an air pollution control ordinance establishing districts in each county. The district boundaries are coextensive with county boundaries and can be activated by the county boards of supervisors. Districts are operating under this act in Los Angeles County and in Santa Clara County. Kentucky adopted a similar law in 1952, and in the same year the Louisville-Jefferson County district was established to supersede the Louisville organization which had been powerless to act against important sources of pollution outside the city limits. Milwaukee County, Wis., and Allegheny County, Pa., also have countywide air pollution laws.

Dr. Woodward is sanitary engineer in charge of the Water Treatment Unit at the Robert A. Taft Sanitary Engineering Center, Public Health Service. During 1953-54 he was with the center's Planning and Evaluation Unit and worked on the development of the air pollution research program. This paper was presented at the annual meeting of the American Society of Civil Engineers in New York City, October 1954.

Need for State Action

In a number of instances the county is not an ideal unit for air pollution control work. In the San Francisco Bay area, for example, nine counties are involved. Many other metropolitan areas include parts of more than one county.

Moreover, although air pollution problems

are generally associated with large cities, they are not limited to them. Damage to crops, to other vegetation, and to cattle by fumes from smelters and other industrial installations have been the cause of considerable litigation. Many industrial installations are located in rural areas where there is no effective agency for air pollution control, and virtually the only remedy available to persons affected has been through direct court action.

Many parallels, legal and other, exist between the problems of air pollution and water pollution. Both are basically economic problems and both require a considerable amount of technical knowledge and skill for their solution. Both air and water pollution are to some extent inevitable and determinations must be made of what degree of pollution is to be tolerated and how pollution is to be abated or prevented. Both are continuing problems which require continuous positive action on the part of waste producers if pollution is to be kept within acceptable limits.

Air pollution and water pollution have important differences as well as similarities, and in some respects the air pollution problem is far more complicated. However, it is apparent that direct court action by the damaged parties is not an effective method of attacking either problem. In view of the position of the States under our form of government, the State is the logical unit for adoption of laws, development of programs, and assistance to local governmental units in the actual abatement of pollution.

One of the major fields in which there is need for State action is the provision of specialized technical services. A compilation of the expenditures of local air pollution control agencies made by the Air Pollution Control Association in 1952 showed that only 17 cities had budgets of \$25,000 per year or more (1). Only nine cities spent more than 15 cents per capita per year, the maximum being 35 cents per capita. In most communities, at least half of the personnel are inspectors. Thus, only the large cities are able, with present appropriations, to support more than the most rudimentary laboratory facilities for sampling and analyzing air to provide the basic information

needed to assess problems or to support the technical staff needed to prescribe solutions to other than routine problems. The smallest city spending as much as \$25,000 per year in 1952 was Syracuse, N. Y., with a population of 220,000. Even so small a city will probably need considerable outside technical assistance in dealing with certain problems.

Survey of State Activities

The communities naturally look to State agencies for technical assistance and in most States some attempt is made to fill this need. A survey recently completed by the Robert A. Taft Sanitary Engineering Center indicates that in all but seven States some attempt is made to assist local governments in solving air pollution problems. As a rule the State agency most active in this field is the health department. In a few States, such as New York, the labor department is active, and in others State-supported universities provide technical assistance to communities and industries.

In most States, however, these activities are only incidental to other work, and no specific financial support is provided for air pollution consultation, technical assistance, or control activities. In six States an agency has either an effective legislative mandate with respect to air pollution, specific executive authorization, or funds earmarked for this purpose. From this, it is obvious that in a majority of the States the activities of the agency are severely limited by lack of funds.

All of the State laws regarding air pollution other than the ordinary nuisance laws are relatively new and reflect the increasing interest and concern which have been particularly marked since the end of World War II. This same increase in interest is shown by the fact that about 80 percent of the local ordinances in effect in our larger cities have been adopted or revised in this same period.

Three States, Oregon, Massachusetts, and New Jersey, have laws establishing air pollution control agencies in the State government. In Oregon and New Jersey, an air pollution control commission or authority is established within the State health department. In Massa-

chusetts the law places authority and responsibility in the health department without specifying the internal organizational unit for the activity. The division of sanitary engineering will, however, be responsible for air pollution control work under this law. The division of smoke inspection, formerly under the department of public utilities, was transferred to the health department and is continuing its work in the metropolitan Boston area.

Oregon's law, the first of the three, was passed in 1951. The Massachusetts and New Jersey laws were adopted in June and September 1954, respectively. All three of the laws give the State agency power to promulgate rules and regulations aimed at preventing or controlling air pollution and outline procedures for dealing with violations. Although in each case the State health department administers the law, the agency is not limited to considerations of the effects of air pollution on health.

The Massachusetts and New Jersey laws deal with the relationships between the State agency and local governmental air pollution control organizations in some detail. The Oregon law gives the authority to advise, consult, and cooperate with such groups and to encourage activity against air pollution. In Massachusetts, local agencies are authorized to regulate air pollution within their respective areas, with their rules and regulations being subject to approval by the State health department. If air pollution from one community adversely affects another, the State health department is authorized, upon request of the affected community and after a hearing with the parties concerned, to assume joint jurisdiction in dealing with the problem.

The New Jersey law authorizes the State Air Pollution Control Commission to organize county air pollution control commissions with advisory functions and also provides that the law shall not supersede local ordinances and regulations nor preclude the right of local agencies to adopt ordinances and regulations which are not inconsistent with the State law.

The Massachusetts and New Jersey laws have been passed so recently that there has been no experience with their operation. The Oregon Air Pollution Authority currently

operates on a biennial budget of \$85,000 with a staff of 4 engineers, 1 chemist, and 1 stenographer and is authorized to develop a comprehensive program for air pollution control throughout the State. The staff has engaged in broad studies of the air pollution problem of the State as well as in investigations of specific problems brought to its attention by complaints. Experience to date has indicated a need for extension of the State air sampling activities and for the adoption of local ordinances to cope with air pollution problems within cities.

Maryland and Pennsylvania maintain units within the industrial hygiene bureaus of their health departments with specific responsibilities for investigation, consultation, and assistance to local agencies on air pollution problems. The Maryland unit, although only partially staffed, has provided assistance to a number of communities. The Pennsylvania unit is well equipped with two mobile laboratories for conducting studies and has investigated a number of air pollution problems throughout the State.

In Washington a different scheme has been adopted. The environmental research laboratory of the University of Washington was established in 1951 and has conducted a number of studies of air pollution problems on a fee basis for both public agencies and private sponsors. The Washington Institute of Technology has conducted research on the effects of air pollution on animal life and vegetation. On May 15, 1954, funds were made available by the Governor, and a statewide air pollution advisory service, which can provide assistance to local governments without requiring direct financial support from them, was established. This service is organized with the director of the Washington Pollution Control Commission as the State official cognizant of all air pollution activities, the environmental research laboratory as technical consultants on community health and welfare aspects of air pollution, the Washington Institute of Technology as technical consultants on the agricultural aspects of air pollution, and the air pollution committee of the Washington State Health Council as a general policymaking group.

In addition to these State activities, a number of States have considered legislation on air pollution, and several have established legislative committees or commissions to consider the need for legislation on the subject during the past 5 years. At least 16 States are known to have had some air pollution legislation or resolution under consideration in recent years.

One interstate air pollution problem has been the subject of State legislation. The New York legislature during its 1954 session passed a bill appropriating \$30,000 for use by the Interstate Sanitation Commission in studying the air pollution problem in the New York metropolitan area and developing recommendations for coping with this interstate problem. The act is to take effect when New Jersey makes a similar appropriation. The companion legislation in New Jersey has not been passed. Similar legislation was passed in 1952 by New York but not by New Jersey.

Summary

Since the end of World War II there has been a marked increase in interest in air pollution and in activities aimed at its control. Although the problem has been traditionally considered one for local action, in many places the need

for State assistance to local governments has become apparent. State assistance is also needed to deal with problems when local control agencies are nonexistent or powerless to act because of lack of jurisdiction.

Three States, Oregon, Massachusetts, and New Jersey, have recently established air pollution control agencies in their State health departments with power to control air pollution. Three other States, Maryland, Pennsylvania, and Washington, have provided funds specifically for investigations of air pollution problems and assistance to local agencies.

In most of the other States, some agency, generally the health department, provides assistance to local agencies incidental to other operations, but such assistance is severely limited by the lack of any specific financial support for the work. In a number of these States, legislation dealing with air pollution has been considered recently. There is a trend toward increasing activity by State agencies in the air pollution field.

Mental Health Panel Discussion Kit

Portions of the film, *Preface to Life*, have been selected for a mental health panel discussion kit, for use on television or at meetings. The kit includes 135 feet of 16 mm. sound film, on a 400-foot reel in a 400-foot can, and 6 copies of an outline of topics, for use as a guide in presenting a half-hour panel discussion.

Single copies of the outline are available at no charge from the National Institute of Mental Health, Public Health Service, Bethesda 14, Md.

Ownership and Size of Nursing Homes

By JERRY SOLON, M.A., and ANNA MAE BANEY, B.A.

THE HISTORY of nursing homes in this country has led to a particular pattern in their ownership and size. Most nursing homes are proprietary. Linked to this type of ownership is the typically small bed capacity of these establishments. It is our purpose here to see just what is the size of existing nursing homes, how many of these homes are operated commercially, or how many are under voluntary and public auspices, and how these two features of ownership and size are interrelated.

We will be primarily concerned with the 7,000 establishments described in the parent report of this study as "skilled nursing homes" (1). The national inventory of nursing homes and related facilities on which this study is based set these skilled nursing homes in perspective within a broad family of facilities. Along with skilled nursing homes, the inventory included "personal care homes," some offering skilled nursing and some not, as well as "sheltered homes." As in the earlier report, these related

types of facilities will be drawn in for comparative data.

So rapidly has the nursing home developed during the past 20 years that its history seems more like an eruption than an evolutionary development. Its rapid growth was influenced by the convergence of a number of social and economic circumstances. The principal ones can only be mentioned here in passing. They include the extension of the life span and marked increase of the aged population, changes in family structure and in living arrangements which have tended toward shelving of the older people, and the growing prominence of the chronic diseases, among both young and old. Although the social and biological factors are the basic elements which combined to create a need, their effect was precipitated by additional important elements. Perhaps the most important among these was the disrepute into which the public almshouse had fallen and the emergence of a new philosophy in public welfare in the Social Security Act of 1935. When society turned from almshouses and chose to place cash assistance in the hands of the needy aged, the resulting expanded demand for private living quarters for older people, many of them infirm or ailing, stimulated a significant response.

The easiest and quickest response came from sources requiring the least immediate outlay in capital and organization. Expediency led to widespread use of existing family structures, not otherwise fully occupied, with the homeowner or lessee often having an applicable skill such as nursing and an interest in such an ac-

Mr. Solon and Miss Baney, health program analysts in the Division of Hospital Facilities, Public Health Service, present their second report on the national inventory of nursing homes and related facilities. The first report, which appeared in the December 1954 issue of Public Health Reports, p. 1121, introduced overall national estimates and an analysis of the distribution of facilities among States and Territories.

tivity as a source of income. Here then was an opportunity for small proprietary ventures.

Some actually started as nursing homes. Some started as boarding homes for elderly people. But in historical background, even as in contemporary operation, the line between homes which offered nursing care and those which provided domiciliary services was not sharply drawn. With the passage of time, homes which had begun as room-and-board enterprises gradually, sometimes imperceptibly, assumed responsibility for meeting personal care and nursing needs as these arose among their aging residents. Thus, many of today's nursing homes are yesterday's small private boarding homes for older people. The current nursing home situation with respect to ownership and size reveals the imprint of these origins.

Ownership of Skilled Nursing Homes

Nursing home is often understood in common parlance to mean private nursing home. This association almost justifies itself, for fully 91 percent of all skilled nursing homes are operated under private commercial ownership.

As though to reinforce this popular identification, the nonprofit voluntary and public institutions have historically been known by other names. Although a nursing home by any name is no less a nursing home, it is often not thought of as such when it bears the label "home for the aged" or "chronic disease hospital" or "county home."

In the present study, institutions are classified by their function regardless of type of name. The resulting facts about skilled nursing homes show that 6 percent are under voluntary (private nonprofit) auspices, of which one-third are church related. Public (State and local governmental) auspices account for 3 percent of the homes.

The picture is somewhat deceptive with these figures alone. The number of beds provided in each category of ownership has an additional significance. Because the voluntary and public homes are typically larger than the proprietary homes, they account for more beds than their small number would suggest (fig. 1). Although

Figure 1. Distribution of skilled nursing homes and beds by type of ownership, 1954.

representing together only 1 home in every 10, they provide 3 beds out of every 10. Thus, the predominance of proprietary ownership, 91 percent in terms of number of homes, is abbreviated to 71 percent in terms of number of beds.

The preponderance of proprietary skilled nursing homes is observed over and over again in the individual States (table 1). It is true that in a number of States there are relatively few proprietary skilled nursing homes or even none at all. However, these are generally States with few establishments all told. It should be mentioned here, however, that since detailed field surveys were not requested of the States for the purpose of the present inventory, the data reported for some individual States may not be wholly reliable.

Ownership of Related Facilities

Proprietary ownership is relatively less prominent in personal care homes and sheltered homes. In those categories, the voluntary and public auspices are traditionally more active than they are in skilled nursing homes (table 2).

Care Homes With Skilled Nursing

Among the several types of facilities related to skilled nursing homes, it is only in personal care homes with skilled nursing that voluntary sponsorship exceeds the proprietary in number of beds provided. Both secular and church groups have developed their programs quite

¹ Virgin Islands did not report. Kentucky's total of 149 homes with 2,604 beds could not be classified by type of facility, for lack of information on level of service. ² Includes one home (22 beds) of unknown ownership. ³ Incomplete figure. Number of beds not reported for some homes (21 homes in Florida, 28

homes in Illinois, 1 home in Mississippi, and proportionately negligible numbers in 5 other States). ⁴ Probably incomplete. ⁵ May be under-reported since a considerable number of homes were not identified as to type of facility.

NOTE: A dash (—) represents "not known."

With 91 percent of all skilled nursing homes under proprietary operation, the popular conception of the nursing home as a small private establishment is objectively accurate. This conception, however, should not cloud the significant, though smaller, role of voluntary and public auspices in this type of facility. Although these nonprofit interests represent only

1 home in 10, they provide, as a result of their usually larger size, 3 beds of every 10.

Definition of Sanitary Engineer Revised

A revision of the 1943 definition of the term, "sanitary engineer," was approved by the Committee on Sanitary Engineering and Environment of the National Research Council, December 14, 1954. The new definition follows.

The professional occupational title "sanitary engineer" shall apply to a graduate of a full 4-year, or longer, course leading to a bachelor's, or higher, degree, with the qualifications noted below, at an educational institution of recognized standing, as defined below, with major study in engineering, who has fitted himself by suitable specialized training, study, and experience (a) to conceive, design, appraise, direct, and manage engineering works and projects developed, as a whole or in part, for the protection and promotion of the public health, particularly as it relates to the improvement of man's environment, and (b) to investigate and correct engineering works and other projects that are capable of injury to the public health by being or becoming faulty in conception, design, direction, or management.

Persons lacking in formal education who otherwise meet the terms of the above definition may be considered as having the equivalent of a full 4-year course in engineering

in an educational institution of recognized standing provided they are registered engineers and have sufficient experience or training of the type defined above to substitute for the engineering education lacking. The basis of such substitution shall be 2 years of appropriate training or experience for 1 year of formal engineering education.

An educational institution of recognized standing is defined as one which is accredited by a national or regional accrediting association, such as the Association of American Universities, or the New England, Middle States, North Central, Southern, or Northwest Association of Secondary and Higher Schools, or one whose professional curriculum has been accredited by the Engineers' Council for Professional Development of the Committee on Professional Education, American Public Health Association.

The practice of sanitary engineering includes the following activities:

1. Surveys, reports, designs, reviews, direction, management, operation, and investigation of works or programs for:

(a) Water supply, treatment, and distribution.

(b) The collection, treatment, and disposal of community wastes,

viz., sanitary sewage, industrial wastes, and refuse, including salvage and reclamation of useful components of such wastes.

(c) The control of pollution of surface waterways and ground waters, and of surface and subsurface soils.

(d) Milk and food sanitation.

(e) Housing and institutional sanitation.

(f) Insect and vermin control or eradication.

(g) Rural, camp, and recreation place sanitation.

(h) The control of atmospheric pollution and air quality, and of light, noise, vibration, and toxic materials, including application to work spaces in industrial establishments (including hygiene engineering).

(i) The prevention of radiation exposure.

(j) Other fields that have as their major objective the control of environmental factors affecting health.

2. Professional research and development work supporting the activities listed in 1.

3. Responsible teaching of sanitary engineering subjects in educational institutions of recognized standing.

Rocky Mountain Spotted Fever Incidence

Until 1931 more than 99 percent of all cases of Rocky Mountain spotted fever reported in the United States occurred in the Mountain and Pacific States where the disease had been known as early as 1873. Prior to 1931 only a few scattered cases had been reported in the North Central States. An investigation of endemic typhus fever in eastern United States, begun in 1930, established the existence of Rocky Mountain spotted fever in the southeastern part of the country. Cases were reported for the first time in the South Atlantic and East South Central States in 1931.

The proportion of reported cases by geographic areas in each 5-year period, beginning with 1930-34 and ending with 1950-54, is shown in the accompanying chart. During this 25-year period, there was a marked reduction in percentage of cases occurring in the Mountain and Pacific States and an increasing proportion in other parts of the country, particularly in the South Atlantic States.

Attack rates per 100,000 population for the various areas by 5-year periods indicate that the peak in incidence of reported cases was reached in the Mountain and Pacific States in the 1930-34 period. Since then, the rate has declined about 80

percent. To what extent vaccination, commenced in 1925 on an experimental basis, has been effective in reducing incidence in these areas is not known.

Since 1930 the disease has been reported in all but two States, Maine and Vermont. Only a few scattered cases have been reported in the remaining New England States. In the western part of the country, incidence rates, based on reported cases, have been highest in Wyoming, Montana, Idaho, and Oregon,

in the order named. In eastern United States, Maryland, Virginia, and North Carolina have experienced the highest rates. However, rates in these States have been lower than in the western States noted above.

Prior to the advent of antibiotic treatment of Rocky Mountain spotted fever, the fatality rate for the country as a whole averaged about 18 percent. With extensive use of these therapeutic agents, which began in about 1949, the fatality rate dropped to about 6 or 7 percent.

Proportion of cases of Rocky Mountain spotted fever reported by geographic areas, 1930-54.

Prepared by the National Office of Vital Statistics, Public Health Service.

The Yale Study in Public Health Administration

More people enter public health because of chance and as a result of personal contacts with public health workers than for any other reasons. Other important motivating factors are work content and working conditions. Education and training are relatively less important. Formal vocational counseling plays a negligible role in recruitment for public health.

Most public health workers do not enter public health at the beginning of their careers; about one-third have had 10 or more years' experience in other fields before coming to public health. Such experience commonly has been in hospitals and related institutions or in business and industry. Physicians and nurses tend to have had hospital experience, whereas other personnel have worked in business or industry.

There is relatively little movement of public health workers from agency to agency, or even from job to job within the same agency.

The majority of public health workers are college graduates. More than one-quarter have graduate degrees; about one-third of these degrees are in public health. In collegiate and graduate education, emphasis has been on the natural sciences. Ten percent of the workers have had no formal education beyond high school.

The public health worker spends one-third of his time in direct service activities, one-third in administration and community relations and organization, and the remaining one-third of the time in routine, stereotyped activities.

Most public health workers are happy to be in public health. However, one-seventh of the workers are unhappy about public health work in general. The greatest single source of satisfaction for public health workers is not in their jobs but in their associates. Major sources of dissatisfaction are inadequate salaries, excessive clerical work, inadequate work facilities, lack of recognition and appreciation in the agency, lack of opportunity for advancement, lack of responsibility and freedom of action, and the absence of a "sense of belonging" in the agency.

These and many related findings were obtained in a study of public health administration, known as the Yale Public Health Personnel Research Project. The study was initiated in 1950 by a research team of the Department of Public Health at Yale University and was supported by research grants from the National Institutes of Health, Public Health Service, and the National Tuberculosis Association.

Perhaps as important as the findings of the study were the exploration and development of methods by which such studies could be conducted. The project showed some of the things that could be done in administrative research of this nature and, also, some of the things that

could not be done. It differed from past research in that its focus was the public health worker rather than the public health program. Its purpose was to study the backgrounds of public health workers, their activities, and their reactions to their jobs.

The study was motivated by the conviction that the information sought was essential to successful recruitment and efficient utilization of public health personnel. Both are of crucial importance in the face of existing shortages of qualified public health personnel.

The methods employed and some of the findings of this research are being published in a series of papers in *Public Health Reports*.

a method for studying

The Public Health Worker and His Job

By EDWARD M. COHART, M.D., WILLIAM R. WILLARD, M.D.,
and WILLIAM McC. HISCOCK, M.A.

THE YALE Public Health Personnel Research Project undertook to provide comprehensive knowledge of the professional public health worker and his job. Information on what the public health worker does was the major objective, but information on his training and experience, his working relationships with persons inside and outside his agency, and his personal feelings about his job was also sought. Such information, it was believed, would be useful in obtaining more efficient utilization of personnel and perhaps in recruiting and training workers, in program planning, and in personnel administration.

Job analysis, of course, is not new. The literature contains countless reports of studies of this type in industry and government. But these studies usually have been restricted to stereotyped jobs with routine work patterns. Moreover, the literature failed to reveal any comprehensive approach to the problems of job analysis and utilization of personnel in the pub-

lic health field. The work that had been done had one or more of the following orientations: concern with a specific geographic area, interest in one discipline, study of one or a few agencies, or a focus on either time or salary. Development of a method of study, therefore, was a necessary part of the Yale project.

The initial focus of the project was the health officer. As it became evident that no one job could be studied properly without regard to interrelationships between jobs, however, the scope was enlarged to include other categories of public health personnel. Furthermore, the sphere of interest in each category was broadened as the possibilities for gaining useful information became apparent. The study was concerned primarily with personnel in official agencies, but a small number of voluntary agency personnel participated also.

Originally, it was thought that it would be possible to obtain composite job descriptions at relatively small cost from an analysis of existing job descriptions. The files of public health job descriptions in the States, maintained by the Bureau of State Services of the Public Health Service in connection with grant-in-aid merit system requirements, were studied. This procedure proved unsuccessful because job descriptions rarely describe the actual job.

Therefore, a plan was substituted to study firsthand the job activities of the several categories of workers in selected State and local health departments. It was decided to conduct this investigation by interviews, occasional

Dr. Cohart is associate professor of public health, department of public health, Yale University School of Medicine. Dr. Willard, formerly associate professor of public health at Yale, has been dean of the College of Medicine at Syracuse, State University of New York, since 1951. Mr. Hiscock was a research assistant in public health at the Yale University School of Medicine and is now assistant medical director, Welfare and Retirement Fund, United Mine Workers of America.

observations, and time studies. The time-study methodology is discussed in a separate article.

The Code

In order to standardize the interview and to process the information obtained, it was necessary to construct a system of classification. Trial questionnaires were used as a point of departure. On the basis of the information gathered by their use, separate codes were developed for the major service groups in public health. These codes emphasized the differences among the services, which seem to be so important in traditional public health thinking.

After more than a year's experience with these codes, it became evident that it would be impossible to analyze the data except in a very restricted service context. It was necessary, therefore, to identify the characteristics which the codes had in common, with the objective of converting the different schemes of classification into one system which would be applicable to all public health personnel.

A single code, called the universal code, was constructed. A document of approximately 100 pages, this code provides for the classification of thousands of items relating to the activities and experiences of public health workers on the job and to their prior education and training. It makes comparisons possible among the several categories of public health workers.

Provisions were made for coding and classifying in detail the following categories of data: (a) identifying information, (b) education and training, (c) experience, (d) ambitions, objectives, and feelings about the job, (e) technical or direct service activities, (f) ancillary or supporting activities, (g) travel, telephone, and correspondence, (h) activities in administration, including supervision and management, (i) working relationships within the agency and with other agencies, and (j) activities related to public education and community organization.

The Interview

The basic pattern for interviewing was non-directive. However, while the interviewee was always encouraged to talk freely, a judicious

question or a brief comment by the interviewer assured inclusion of the desired areas of coverage. Interviewers were required to master the code before undertaking field interviews in order that they might conduct the interview without constant reference to lists of questions. The code was available at the interview, and it was used frequently to demonstrate to the interviewee the type of information desired.

To some extent the technique of the interview was determined by the person being interviewed. Some individuals talk freely and easily; others have to be prompted or directed. The interview tended to be more directive with workers engaged in semiroutine jobs than with those in nonroutine jobs. Even at such interviews, however, questions were open-end in nature and were presented so as not to indicate that a particular answer was being sought.

When a new member joined the research staff of the project, he underwent a supervised training period. This included familiarization with the code and the data to be obtained in interviewing, and review and testing of actual

interview techniques. For the first few weeks, the new member's interview experiences were reviewed by other staff members.

Particularly valuable to the maintenance of uniformity was the assignment of two or more interviewers to the same agency. This procedure made it possible for the interviewers to hold frequent discussions about the problems encountered in interviews, the interpretation and coding of the data, and the use of interview techniques. These team discussions helped to minimize interviewer biases and idiosyncracies. They also resulted in additional suggestions for the analysis of project data.

The conduct of the interview was such that the participants were made to feel that this was "their study," and they were assured that all personal and specific information was confidential and would not reach the ears of their fellow workers or administrative superiors. It was

stressed that the study was not an evaluation, but an inventory. These circumstances, we feel, contributed to greater frankness and veracity in the responses. Furthermore, the interview, by its very nature, permitted of explanation and definition which clarified both questions and responses and enhanced the validity of the resulting data.

About 9 or 10 hours were required for each person interviewed. An average of 3 hours was spent in conducting the interview; approximately 3 hours, in recording and coding the interview information; and the remaining time, in preinterview discussions and conferences, in participation in public relations, in travel, and in project housekeeping functions.

Considerably more than 10 hours per person were required, however, for personnel in voluntary health agencies. The difficulties of making contacts and obtaining clearance for the

conduct of the study in each voluntary agency, the fact that these agencies were scattered throughout the State, and the small number of workers in any one organization, all contributed to this situation. The research staff found that introductions to State offices from national offices, and to local from State, were not particularly helpful. In each agency, much time was needed to explain the project to the participants and to obtain clearance from various boards and trustees.

Selection of the Sample

Two proposals for selecting the sample to be studied were advanced: one, that the sample be selected at random from all health departments; and the other, that the sample be selected on the basis of geography, size of the agency, and the urban or rural nature of the population served from only "good," or "better than average," agencies. Discussions concerning the relative merits of the two proposals produced a decision to use the latter. The project thus became a field investigation to inventory the activities and backgrounds of public health workers in selected "better than average" State and local health departments in the United States.

"Better than average" health departments were chosen on the basis of the value judgments of the consultants and advisers to the project. The basic criteria used were the comprehensiveness of the public health program, the adequacy of the public health staff to serve the area and its population, and the quality of staff performance. Selection was made as the result of consideration of many factors, and, therefore, "inferior" as well as "superior" practices were found in the agencies chosen.

The judgment of the State health officer and the director of local health services was relied upon for the selection of local units within each State. These judgments sometimes were augmented by the opinions of a conference committee of local health officers.

Composition of the Sample

The project obtained information on 1,648 persons actively engaged in public health enter-

¹ In Connecticut, Maryland, Michigan, and New York, which comprised the sample used in most of the analyses of the data.

prises in Colorado, Connecticut, Florida, Maryland, Michigan, and New York. Of these, 1,608 were employed in official agencies and visiting nurse associations, and 40 in voluntary health agencies. (Unless otherwise stated, the term

"local health departments" is used in this report to include visiting nurse associations.) The cooperation of the participating agencies was particularly gratifying.

The geographic distribution of the sample (with the exception of the 40 persons in voluntary health agencies) can be seen in table 1. Since Colorado and Florida were visited early in the course of the project, coverage was incomplete in these States in light of the criteria eventually established for the selection of personnel and the nature of the information to be elicited. Therefore, data obtained from these States were not included in most of the analyses.

Included in the study were all full-time, paid public health workers with professional, technical, or administrative responsibility for public health administration. Generally excluded were persons whose responsibilities were limited to clinical medicine, research, or hospital management or whose activities were uncommon in public health or were strictly routine. On this basis, most clerical workers were excluded, but secretaries with technical or administrative responsibilities were included.

If two or more employees performed essentially the same activities, only one of them was interviewed as representative of the group. The job activity information for this representative worker was duplicated for each worker with similar activities. As a result, it was possible to gain the desired information about the activities of the 1,303 persons who comprise the sample used in most of the analyses by interviewing 752, or 58 percent of them.

The personnel studied belonged to the medical, dental, nursing, sanitation, administration, health education, statistics, laboratory, secretarial, nutrition, social work, and venereal disease investigation services. The term service as used in this study refers to an administrative unit defined by the methods employed rather than the programs pursued. Services are frequently but not always synonymous with discipline. Thus, most nurses are members of a nursing service, but an occasional nurse is engaged in health education, hospital administration, or sanitation, for example.

The service classification of the participants in this study is shown in table 2. In terms of numbers, the major services in both State and local health departments were medical, nursing, sanitation, laboratory, and secretarial.

Position in the hierarchy of the organization also was used in the comparison of the various activities of public health workers. The composition of the sample according to administrative level is shown in table 3. For most purposes comparisons were made between high-echelon and staff personnel, but in some instances the executive and supervisor-consultant subdivisions of high-echelon personnel were used.

Summary and Conclusions

The Yale Public Health Personnel Research Project was aimed at determining the activities of public health workers, their backgrounds,

and their personal reactions to their jobs. The study was an inventory, not an evaluation. In the course of the project, problems of scope, sampling, and method were encountered and were resolved more or less satisfactorily.

Interviews, with a minimum of formal direction on the part of the interviewer, were used to obtain information from the participants. A detailed universal code was developed for classifying the data, after it became evident by trial that the use of a separate code for each of several categories of personnel would limit the possibility of making comparisons.

The health departments participating in the

study were chosen as representative of "better than average" agencies. Because of the sample used, the findings may not necessarily have broad application to public health practice in the United States, but we think they do add to our meager knowledge.

One great handicap under which the project labored was the failure to provide for a complete pilot run before the major data-gathering commitments were undertaken. The development and testing of the investigative instruments and methods proved to be more significant in this study than the collecting of data.

Venereal Disease Among Teen-Agers

—Its Relationship to Juvenile Delinquency—

By JAMES F. DONOHUE, B.S., M.P.H., GERALDINE A. GLEESON, A.B.,
KENNETH H. JENKINS, B.S., and ELEANOR V. PRICE

LIMITATION of funds and personnel for venereal disease control has made it necessary to pinpoint insofar as possible the segments of the population in which venereal disease occurs most often and to which epidemiology can most effectively and profitably be applied. With this major objective, a project was initiated to collect morbidity data by age since up to this time only scattered information was available as to the age composition of reported cases.

With increasing attention being given to problems of youth, such data would also provide an opportunity to study the venereal disease problem among teen-agers. In addition, it was deemed important to determine the relative frequency of reported venereal disease among young adults as compared to older persons. It was anticipated that the findings from the analysis of these data would greatly increase our knowledge of the venereal disease problem, improve our case-finding efficiency, and heighten the accuracy of our estimates of the incidence and prevalence of syphilis and gonorrhea.

Mr. Donohue is chief statistician and Mrs. Gleeson, Mr. Jenkins, and Mrs. Price are statisticians in the Venereal Disease Program, Division of Special Health Services, Public Health Service. This paper is based on morbidity data furnished by State and city health departments.

Morbidity reports routinely submitted by State and city health departments indicate the number of cases reported by disease, stage of disease, race, sex, and reporting source, but do not provide any information relating to age. Reporting areas were therefore requested to prepare a special report of venereal disease cases by single years of age for all syphilis and gonorrhea cases reported in the calendar year 1953.

Response to this request was quite gratifying. Only one State and one large city were not able to submit tabulations by age. In terms of total cases, based on routine morbidity reports, 83 percent of syphilis cases and 77 percent of gonorrhea cases were reported by individual year of age. For purposes of this study, cases of unknown age have been prorated on the basis of known age distributions.

This report, the first to be published on this study, will consider in general that portion of the venereal disease problem which occurs among persons under 20 years of age and will relate these data to juvenile delinquency and other problems of youth.

Figure 1 shows the general pattern of the age distribution of the total cases of syphilis (all stages) and gonorrhea in the United States by 5-year age groups. A glance at the chart shows that the curve is peaked at the 20-24 year age group and is skewed to the right. The abrupt increase in cases at ages 15-19 years indicates how very serious the venereal disease problem is after age 14.

Figure 1. Total cases of syphilis and gonorrhea reported in continental United States for the calendar year 1953, by age.

Epidemiology and the principles of preventive medicine can be applied most productively to the infectious stages of venereal disease. Figure 2 shows the age distribution of primary and secondary syphilis and gonorrhea by 5-year age groups. A higher proportion of the venereal disease cases in this chart are in the younger age groups than in figure 1 since syphilis cases of long duration are excluded. The chart represents the age distribution of fresh cases of venereal infections. Again there is a sharp increase in cases in the group aged 15-19 years.

Figure 2. Cases of primary and secondary syphilis and gonorrhea reported in continental United States in the calendar year 1953, by age.

It will be noted from table 1 that 22.4 percent of infectious venereal disease in the United States is reported among persons under 20 years of age. The proportion that infectious venereal disease is of the total syphilis and gonorrhea reported at any given year of age is also shown in table 1. It will be observed that this percentage increases from age 11 to a maximum at age 18 and then gradually decreases with age. Although this percentage represents all infectious venereal disease, it is believed that most of the infections at age 10 and below were probably acquired innocently.

Figure 3. Percentage of total cases of infectious venereal disease reported among persons under 20 years of age, by race and sex.

Infectious Venereal Disease Under Age 20

Infectious venereal disease is diagnosed more often among males than among females because of more obvious signs or painful symptoms in the male. However, blood testing surveys have shown that both sexes have equal syphilis prevalence rates. Another factor which must be considered is the very significant difference in both incidence and prevalence of venereal disease between whites and nonwhites. In analyzing the relative frequency of infectious venereal disease reported among teen-agers we must compare the number of cases under age 20 in each race-sex group with the total number of cases for that group to demonstrate how the percentage of infectious venereal disease under age 20 varies among the four race-sex groups.

Figure 3 shows how the percentage of infectious venereal disease in persons under age 20 varies with sex and race. The proportion of cases in this age group ranges from less than 12 percent among white males to more than 34 percent among nonwhite females. Females of both races have a higher proportion of cases in per-

sons under 20 years of age than do males, and for each sex, the rate for nonwhites is higher than the rate for whites. This is true for every State as well as for the Nation as a whole. Table 2 shows the percentage of infectious venereal disease cases for males and for females under age 20 for each of the 47 States participating in the study. Wide ranges occur between States, and percentages for all teen-agers vary from 9.6 percent to 33.9 percent.

Figure 4 presents the percentage of infectious venereal disease among persons under 20 years of age in the various States. It shows that the greater proportions by and large coincide with the States having the greater total venereal disease problems. These States have characteristically operated vigorous control programs

during the past decade, but their socioeconomic levels and the age and race distributions of their populations have placed them in a relatively unfavorable, although improving, situation with respect to most health problems. The high percentages of venereal disease among teen-agers in these areas are therefore a valid measure of how far the venereal disease control programs in these States have yet to go before the venereal disease aspect of their total youth problem compares favorably with that of States having low percentages of infectious venereal disease among their youth. We have used this percentage of infectious venereal disease among persons under 20 years of age as an index of the venereal disease problem among teen-agers, and we have related it to other problems of youth.

N. D.—No data.

Figure 4. Infectious venereal disease among teen-agers in the United States.

Infectious venereal disease reported in persons 10–19 years of age is separated in figure 5 into its two components, primary and secondary syphilis and gonorrhea, in an effort to distinguish sexually acquired from nonsexually acquired infections. It will be observed that the age distribution for primary and secondary syphilis, which is rarely nonsexually acquired,

Table 3 and figure 6 show the cumulative percentages of infectious venereal disease cases in persons 10–19 years of age, by sex. Since there were no appreciable differences in the percentage distributions by race, these data were not shown separately by race. The cumulative percentage of infected females is higher than the cumulative percentage of infected males at

Figure 5. Percentage distribution of cases of primary and secondary syphilis and of gonorrhea reported among males and females aged 10–19 years.

is in general the same as for gonorrhea. In both diseases, the upward swing begins in females at age 12 and in males at age 14, and illustrates the point that infectious venereal disease is sexually acquired at a much earlier age than has been realized. Females have a higher proportion of cases than males in the earlier years up to age 17, at which age the percentage in males becomes higher than in females. As a matter of fact, the 18th year of age is the modal year for all females, whereas the male frequency continues to increase with age into the early twenties. The dip at age 17 among females with primary and secondary syphilis is not explainable unless females at that age claimed to be a year older than they were. This phenomenon does not appear in the gonorrhea distribution, however.

each age from 10 through 18 years. The greatest difference in cumulative percentage is at age 16 where the difference is 15.9 percent. The curves indicate that 50 percent of the females in the group 10–19 years of age become infected by the time they reach the age of 17.5 years whereas 50 percent of the males become infected by the time they reach the age of 18.0 years. The quartile horizontal line shows that 25 percent of the females are infected by age 16.1 years whereas one-fourth of the males become infected by age 17.0 years.

Charts 7–11 are scatter diagrams, which present a graphic picture of the association between infectious venereal disease among teen-agers and certain other problems of youth. The rate (or percentage) of infectious venereal disease cases among persons under 20 years of age in a

State is plotted on the X -axis, and the extent of other youth problems is plotted on the Y -axis. Each point represents a State for which measures of both variables are available.

It should be mentioned that a significant coefficient of correlation does not necessarily indicate a *causal* relationship but does illustrate that a definite association exists between two variables within the same segment of the population.

The degree of association between two series plotted as indicated above is calculated by the correlation method and is measured in relative terms by the coefficient of correlation which ranges in numerical value from 0 to ± 1 . A value of $+1$ would mean that there is a perfect direct relationship, that is, an increase in X results in a definite increase in Y . A value of $r = 0$ would indicate that there is no association whatsoever between the two variables, and a value of $r = -1$ would mean a perfect inverse relationship. Rarely would one expect to find such values of a coefficient correlation computed from actual data. The less perfect the relationship between the two variables, the greater the departures (or scatter) from the line of regression.

All correlations shown in this paper have been tested for statistical significance. All but one were significant at the 1-percent level, meaning that there is less than 1 chance out of 100 of finding such a degree of correlation by

Figure 6. Cumulative percentage distribution of infectious venereal disease reported among males and females aged 10-19 years.

chance in unassociated data. The single exception is the correlation relating venereal disease and illegitimacy (fig. 8), which was significant at the 2-percent level.

It should be mentioned that there is a paucity of statistics on juvenile delinquency which are comparable from State to State. The problem

is that the laws and interpretations of laws concerning juvenile delinquency vary greatly between States. In fact, interpretations vary within States. Variable factors include age, sex, nature of crime, conditions in home, status of parents, intelligence of juvenile, education, probation, court procedures, and so on. Furthermore, there is no standard procedure for reporting juvenile delinquency statistics, and many States do not even have a central reporting agency for juvenile court statistics.

Figure 7. Scatter diagram relating infectious venereal diseases and juvenile delinquency reported by 47 States.

The only available data on juvenile delinquency which are statewide in coverage and which meet the criteria of consistency between States appear in the annual report of the Administrative Office of the United States Courts (1). The number of defendants in criminal proceedings tried under the Juvenile Delinquency Act (Title 18, sec. 5031) in the United States district courts is used as an index of juvenile delinquency in each State. Figure 7 shows the number of cases of infectious venereal disease per 100,000 population under 20 years of age in 47 States plotted against a juvenile delinquency index for each State, based on the number of defendants in criminal proceedings initiated in United States district courts during fiscal year 1954. The coefficient of correlation was equal to plus .631, which indicates a significant positive association between the infectious venereal disease rate among teen-agers and ju-

Figure 8. Scatter diagram relating infectious venereal disease and illegitimacy reported by 32 States.

venile delinquency as represented by the number of criminal proceedings for Federal offenses among the same age group population.

The dependent variables in the remaining figures are statistical data concerning problems of the same population segment as published by the National Office of Vital Statistics and the Census Bureau. In figure 8 the percentage of cases of infectious venereal disease among females under 20 years of age is plotted against the illegitimacy ratio reported in 32 States, which is used as a measure of promiscuity (2). The coefficient of correlation was equal to plus .383, which indicates a positive association between the percentage of infectious venereal disease among female teen-agers and the ratio of illegitimate births per 1,000 live births registered.

Figure 9 shows the percentage of cases of infectious venereal disease among females un-

Figure 9. Scatter diagram relating infectious venereal disease and fetal deaths reported by 46 States.

Figure 10. Scatter diagram relating infectious venereal disease and school enrollment reported by 47 States.

der 20 years of age plotted against the percentage of fetal deaths (abortions, miscarriages, and stillbirths) occurring among mothers under 20 years of age reported by 46 States (2). The coefficient of correlation was plus .549 and indicates that a significant association exists between venereal disease and fetal deaths among teen-age mothers. This does not mean that venereal disease necessarily caused the fetal deaths, although venereal disease among pregnant women can result in disastrous outcome.

The percentage of infectious venereal disease among persons under 20 years of age is plotted in figure 10 against the percentage of the population 14-19 years of age enrolled in school (3) in 47 States. The coefficient of correlation was minus .560, which indicates a significant inverse

Figure 11. Scatter diagram relating infectious venereal disease and extent of low family income, reported by 47 States.

relationship between percentage of school enrollment and the percentage of infectious venereal disease among persons under 20 years of age. This negative association indicates that the higher the percentage of teen-agers in school the lower the venereal disease attack rate among this age group.

Figure 11 shows the percentage of total cases of gonorrhea and primary and secondary syphilis reported among persons under 20 years of age plotted against the percentage of families with incomes of less than \$2,000 per year (3). The coefficient of correlation was plus .691 and indicates that there exists a significant positive association between venereal disease and this measure of financial status. This should be expected since it is well known that the lower the socioeconomic level the higher the venereal disease rate.

Discussion

All the evidence presented points to the fact that there is a definite degree of association between teen-age venereal disease and other problems of youth. The extent of venereal disease among teen-agers varies directly with criminal proceedings for Federal offenses among the same age group, promiscuity among persons under 20 years of age, fetal deaths among teen-age mothers, and lack of financial stability and varies inversely with educational status. This latter point is the one encouraging aspect of the problem since the higher percentage of juveniles enrolled in school, the lower the venereal disease attack rate in this age group.

The meaning of venereal disease among teen-agers might be interpreted in several ways. It could be argued that in a country where there is considerable incidence of infectious venereal disease, it is only natural that sexually active teen-agers account for a substantial proportion of all venereal infections. On the other hand, a youngster infected with a venereal disease has obviously deviated from the accepted pattern of approved social behavior. In this sense, venereal disease itself might be considered a manifestation of the broad problem of juvenile delinquency.

These correlations highlight again an im-

portant phase of the Nation's prospects in the field of health: The protection which adequate income, wise and well-organized communities, and familial and social guidance can give to our American youth has indirect benefits in the field of health. The correlations indicate that venereal disease is but one of the problems to which our less-protected and therefore less-privileged youth is exposed.

Current indications of increases of venereal disease in many States, recent outbreaks of venereal disease involving high percentages of teen-agers, and the extensive juvenile delinquency which has recently been of so much general concern highlight the serious problem which exists in our venereal disease control program and to which our utmost efforts must now be directed.

That the venereal disease program, as well as other health programs, was able during the last decade to make headway in the presence of other youth problems arises largely from the fact that the techniques of case finding, diagnosis, and treatment, vigorously supported with

local, State, and Federal funds, acquired a momentum greater than the speed at which these diseases were transmitted. This reduction in incidence and prevalence of venereal diseases among teen-agers might be envisioned not only as a specific accomplishment in disease control but as part of our total effort toward giving youth protection against the many hazards of growing up; as part of the Nation's effort to create a favorable climate and soil for its most important product.

Legal Note on Commitment of Insane Federal Prisoners

The United States Court of Appeals for the Eighth Circuit, in an opinion dated February 14, 1955, held that any insane or mentally incompetent Federal prisoner may be committed to the custody of the Attorney General regardless of the probable duration of his illness, *Greenwood v. United States*, 23 U. S. L. Week 2411.

This decision is in conflict with prior cases from two other circuits, the 9th and 10th. In the cases of *Wells v. Attorney General*, 201 F. 2d 556 (C. C. A. 9th. 1953), and *Higgins v. United States*, 205 F. 2d 650 (C. C. A. 10th, 1953) it was held that such commitments must be limited to temporarily insane prisoners pending their trial since any attempt by Congress to authorize the commitment of other than temporarily insane prisoners would be

unconstitutional as an invasion of the general field of lunacy which is reserved to the States by the 10th amendment. The *Wells v. Attorney General* case was noted in the August 1953 issue of *Public Health Reports*, page 825.

In the *Greenwood* case, however, the court held that the power to provide for the commitment of insane or incompetent prisoners to the custody of the Attorney General was a necessary incident to the power to provide for the enforcement of the Federal criminal laws. With regard to the invasion of the "general field of lunacy," the court said that: "No valid objection can be based upon the fact that such exercise may be attended by the same incidents which attend the exercise by a State of its police power, or that it may tend to accomplish a similar purpose."

Ophthalmia Neonatorum

By C. A. SMITH, M.D., and LAURA HALSE, M.S., LL.B.

ONE of the most dramatic and heartwarming achievements of the effort to control venereal disease has been the reduction of blindness in babies resulting from infection with gonorrhea by the mother during birth. The great advances in the prevention of ophthalmia neonatorum were made before the era of sulfonamides and the antibiotics; they resulted from the very simple, so it seems now, procedure of placing silver nitrate solution or other effective silver preparation in the eyes of the child immediately after birth. These preparations of little value in treatment once the disease is established, are highly effective in preventing infection in the eye. Simple as the procedure was, its introduction as part of the routine health and medical practice resulted in widespread and inspired activity by various health groups. The story of these efforts will be known in order to understand the infectious and family-in-

Gonorrheal infection in the eye is a so-called gonorrheal ophthalmia. It is swift and severe. If untreated, blindness in a very short time. Without treatment, about 90 percent of infants infected with ophthalmia neonatorum

Dr. Smith is chief of and Mrs. Halse is specialist in the Venereal Disease Program of Special Health Services, Public Health Service, U.S. Department of Health, Education and Welfare.

40
and secondary syphilis
page, 1953

come blind. The most common means of infection is through contact with the mother's eyes during passage through the birth canal. However, infection can also occur if they are contracted from another individual.

Signs of venereal disease and other ailments of youth. The extent of venereal disease among teen-agers varies directly with criminal proceedings for Federal offenses among the same age group, promiscuity among persons under 20 years of age, fetal deaths among teen-age mothers, and lack of financial stability and varies inversely with educational status. This latter point is the one encouraging aspect of the problem since the higher percentage of juveniles enrolled in school, the lower the venereal disease attack rate in this age group.

The meaning of venereal disease among teen-agers might be interpreted in several ways. It could be argued that in a country where there is considerable incidence of infectious venereal disease, it is only natural that sexually active teen-agers account for a substantial proportion of all venereal infections. On the other hand, a youngster infected with a venereal disease has obviously deviated from the accepted pattern of approved social behavior. In this sense, venereal disease itself might be considered a manifestation of the broad problem of juvenile delinquency.

These correlations highlight again an im-

In 1808, Gibson, an English obstetrician, observed a connection between the strange malady known as "babies' sore eyes" and the discharge present in the birth canal of the mother (3). He reported that careful cleansing of the mother's body and the wiping of mucus from the baby's eyes after birth might prevent an infection which often led to lifelong blindness. But his colleagues paid little attention to his advice. At that time, in accordance with prevalent theories on causation of disease, doctors explained to mothers of babies who had lost their eyesight at birth that this condition was due to such causes as the peculiar constitution of the atmosphere or sudden changes of temperature. Colds were assumed to be the cause of inflamed eyes. This belief was so widespread that Cortez, the Spaniard, in 1837 decreed that all babies should be baptized with warm water instead of cold water.

In 1820, Vetch, by experimental inoculation of female genital secretion, was able to produce ocular inflammation, suggesting the truth of Gibson's assertion (4). In 1879, Albert Neisser, an assistant professor in the University Clinic of Dermatology at Breslau, described a micrococcus that he believed to be the cause of gonorrhea (5). His discovery attracted universal attention, coming at a time when the science of bacteriology was developing and numerous investigators in the bacteriological and pathological fields were beginning to carry on research. However, there was considerable doubt in the minds of many scientists as to the rôle played by the gonococcus in the production of gonorrhea. This was finally resolved by experimental genital inoculation of both gonococcal discharge and cultured gonococci. Then, in 1881, Hirschberg and Krouse demonstrated the gonococcus in patients with ophthalmia neonatorum (6).

In spite of discovery of the causative agent of gonococcal infections, therapy for both genital and ocular infections was highly unsatisfactory. The multiplicity of treatment schedules suggested attests to the essential lack of value of any one of them. Thus, as might have been expected, much attention was given to potential means of prevention of ocular infection.

In 1856, Dr. Karl Sigmund Franz Credé was made director of the lying-in-hospital in Leipzig (7). After years of experimental studies, he found an agent which would prevent ophthalmia neonatorum. In 1886 he published his epochal treatise (8) in which he stated, "... if two percent solution of silver nitrate is dropped in the eyes of newborn infants, immediately after birth, the pus germs producing ophthalmia neonatorum could be killed and the development of the disease prevented." His records showed that the disease developed in only 0.17 percent of the cases in which silver nitrate was used, whereas it developed in 10 percent of the cases in which the solution was not used.

Credé's theory and demonstration were not immediately accepted and were, in fact, met by widespread opposition. However, as knowledge of his experience spread, other clinicians began to apply his findings.

In the United States, Dr. Lucien Howe (7) became the leader in the fight against ophthalmia neonatorum. He went to Egypt in 1887 and studied purulent ophthalmia; when he returned to the United States he began his campaign against ophthalmia neonatorum. He established and became the director of the Howe Laboratory of Ophthalmology at Harvard, endowing this institution with \$1 million from his own fortune. He campaigned in many States for passage of legislation and drew up model laws for the prevention of this disease. It was largely through his efforts that early legislation for compulsory instillation of silver nitrate in the eyes of newborn children was passed. Dr. Howe was so forceful in his pleas for prevention of blindness that he aroused the New York State Medical Society and the American Ophthalmology Society to become actively responsible for legal work for the control of the disease.

In 1905, influenced by Dr. Howe, the New York City Health Department sent out a bulletin instructing all midwives in the use of Credé solution of silver nitrate in the eyes of the newborn child. The bulletin also reemphasized that all sore eyes must be reported to the health department so that medical investigation could be instituted and treatment given when necessary.

The Governor of New York was so impressed by Dr. Howe's enthusiasm and energy that in 1906 he appointed him to the Commission to Investigate the Conditions of the Blind. Dr. Howe and Dr. Park Lewis, president of the commission, assisted in promoting a detailed census of the blind in New York State, which they presented to the legislature in 1907 (7). They were also instrumental in establishing the National Society for Prevention of Blindness.

National Society

Included in the report of the census of the blind in New York State was an article by Dr. Lewis entitled "Needlessly Blind," in which, referring to ophthalmia neonatorum, he said ". . . this is a disease the nature of which is fully understood, which might have been controlled or avoided by simple prophylactic or therapeutic measures at the time the infant came into the world."

In 1908, Louise Lee Schuyler read Dr. Lewis' article and became determined to start a movement to acquaint the public with the menace of ophthalmia neonatorum (7), and it was her leadership and intelligence which did so much to popularize the movement and which gave real drive to it. With Edith Holt, she organized groups to discuss ways and means of influencing the legislature and of educating the public in the necessity of using prophylaxis to prevent blindness. Miss Schuyler and Miss Holt then organized the New York State Committee for Prevention of Blindness, a private organization.

It soon became apparent to this committee that blindness was a problem of national importance and in 1915, the National Society for the Prevention of Blindness—a lay organization cooperating actively with the medical profession, particularly ophthalmologists, and with official and volunteer health agencies—was organized. The State committee then became a standing committee of the national society.

The objectives of the national society were:

1. To endeavor to ascertain, through study and investigation, any causes, whether direct or indirect, which may result in blindness or impaired vision.

2. To advocate measures which shall lead to elimination of such causes.

3. To disseminate knowledge concerning all matters pertaining to care and use of the eyes.

In the beginning, the society established a cooperative relationship with agencies and societies, official and volunteer, which had either a direct or an indirect responsibility for the prevention of blindness and the conservation of vision. In 1925, it established such a relationship with the Conference of State and Provincial Health Authorities of North America.

The society prepared and distributed literature of particular interest to ophthalmologists, first securing from them approval of the material, and provided slides and moving pictures for use in lectures. It continues to prepare and distribute literature but no longer has slides and moving pictures available.

In 1928, as a result of educational work by the national society, and recognizing the need for preventive work, the New York Commission for the Blind established a department of prevention of blindness and made Sarah Clendinning, R. N., the director. Under Miss Clendinning's leadership, groups were reached through lectures on the prevention of ophthalmia neonatorum.

Statistics

In 1908, ophthalmia neonatorum was responsible for 28 percent of the blindness among new entrants in blind schools (9). In 1933, 11 percent of the new entrants in these schools were blind from this disease; by 1950 this figure had been reduced to 1 percent.

In 1923, Dr. Taliaferro Clark and Dr. J. W. Kerr of the Public Health Service wrote: "It has been conservatively estimated that ophthalmia neonatorum is responsible for 20 percent of blindness in the United States. Blindness is not a reportable disease; therefore, statistics had to be gathered largely from institutions for the blind throughout the United States. For this reason, the figures compiled represent only those children that are institutionalized in blind schools" (7).

A report issued in 1926 (10) showed that in 1907, 28 percent of the blindness in the United States was due to ophthalmia neonatorum; in

1913-17, blindness from this cause had dropped to 19 percent; in 1918-22, it was 16.5 percent; and by 1926, or within 18 years, a decrease of 51.3 percent had occurred.

Before 1930, the most complete and authentic information on the blind was assembled by the Bureau of the Census (11). However, this information was incomplete. Only a few State commissions had compiled reports of ophthalmological findings. For causes of blindness, the Bureau of the Census could give only data based on the statements made by blind persons themselves instead of reports of ophthalmological examinations. In many ways, the data were inconsistent and inadequate and often were completely lacking. A special conference was called by the American Foundation for the Blind and the National Society for the Prevention of Blindness to discuss methods of improving statistics on blindness. In 1930, the Committee on Statistics of the Blind was organized and still is sponsored and financed jointly by these two groups.

Early Enactments

In 1922, the Sanitary Code of New York City stated (12) “. . . it shall be the duty of every physician, nurse, midwife, or other person in attendance on a confinement case to instill in the eyes of a newborn child immediately after delivery—1 percent solution of silver (nitrate) or an equally effective agent in order to prevent the development of ophthalmia neonatorum.”

In 1926, according to a report by the National Society for the Prevention of Blindness, 20 States had definite enactments requiring the use of prophylaxis in the eyes of every newborn child. (Fifteen of these were Alabama, Arizona, Delaware, Georgia, Idaho, Iowa, Maryland, Michigan, Missouri, Rhode Island, Tennessee, Texas, Virginia, West Virginia, and Wisconsin.) Five States—Indiana, Louisiana, North Dakota, Utah, and Washington—had definite enactments requiring the use of prophylaxis under certain qualifying conditions. In 12 States, regulation was under State board of health rulings; Florida and Montana had no law. Thirty States required that the birth certificate indicate whether or not prophylaxis

was used and the strength of the prophylactic agent.

Control Measures

Public health workers recognize that the general public is not interested in health per se; a desire for good health is not a dynamic force in securing action to attain it. Even the understanding of the cause of a tragic disease is not essential to action. This situation is exemplified in the ophthalmia neonatorum control program. The cause of the disease is gonorrhea in the mother, yet the early campaigners for preventive legislation practically never mentioned this. They issued pamphlets citing the number of children that were “needlessly blind” because of lack of proper medical care. They discussed methods of educating the public to realize the necessity for using prophylactic measures to prevent “babies’ sore eyes” and discussed ways and means of influencing State legislators to pass preventive legislation.

The one exception to this approach was through Dr. William Snow, chairman of the American Social Hygiene Association, an enthusiastic supporter of the program of the National Society for the Prevention of Blindness. He reiterated the known fact that ophthalmia neonatorum would be prevented if gonorrhea were wiped out. At an annual meeting of the American Social Hygiene Association he stated “. . . there are approximately 200,000 blind persons throughout the country and it is estimated that more than 15 percent of those lost their sight because of syphilis and gonorrhea. It is obvious that there is a close relationship between the movement to prevent blindness and the drive to stamp out these diseases.”

The campaign for prevention of blindness in babies was directed by and to the socially and economically secure groups. The support of these articulate and well-informed groups has been an important factor in obtaining legislation which required prophylaxis in the eyes of the newborn child. The campaign to eradicate venereal disease during the years 1920-29, although the opposition was neither specific nor ephemeral, did not parallel the success of the ophthalmia neonatorum prevention program. The venereal disease program appeal was made

primarily to middle-class groups, who at that time were reluctant to discuss publicly "sex and social hygiene."

Perhaps control of blindness among babies depends, in the final analysis, upon motivation of the physician, the nurse, or the midwife only, whereas control of venereal disease depends upon the motivation of many individual patients.

The Public Health Service during this period, 1920-29, cooperated with the States in establishing training services in epidemiological studies and research laboratories to determine the causes of blindness. Data were gathered regarding legal provisions for the prevention of ophthalmia neonatorum. Reports concerning venereal diseases as a cause of blindness were published and distributed to State health departments.

Federal, State, Local

Federal authority in health matters does not extend to participation in the exercise of police powers of the State. Federal authority is concerned with interstate and international health problems. The police powers relating to health, safety, and morals within the State borders have been reserved specifically to the States themselves.

The administration of public health in a State is a significant part of general administration. The physician in charge of a State health department has a dual responsibility in the enforcement of health regulations: he must furnish expert professional advice to the State legislators, and, as an administrative officer in the health department, he must protect the health of the people through the control or eradication of disease.

Pennsylvania's experience illustrates State efforts to control ophthalmia neonatorum. In November 1931, the Pennsylvania State Board of Health began an active campaign against ophthalmia neonatorum (13). A State law had been passed in 1913, but it left the procedures to be worked out and enforced by the State board of health. The board of health had issued regulations making mandatory instillation of one drop of silver nitrate in the eyes of a newborn child, defined "inflammation" of

babies' eyes," and required that any evidence of this infection be reported to the local health department. The 1931 campaign, 18 years after passage of enabling legislation, was the result of the widespread failure of physicians or attendants at childbirth to carry out the provisions regarding instillation of a prophylaxis in the eyes of a newborn child, and to report immediately any indication of "sore eyes in a newborn infant."

In the spring of 1951, it came to the attention of Dr. Theodore Appel, secretary of the State board of health, that, of the total enrollment of 289 children in the Overbrook School for the Blind, 51 were blind as the result of ophthalmia neonatorum; and 6 of 45 children who had entered the school the previous year were blind from ophthalmia neonatorum. This situation occurred in spite of the fact that, in Pennsylvania, application of prophylactic treatment to the eyes of a newborn child was mandatory and that "sore eyes" were reportable. Dr. Appel sent out letters to all county medical officers which said, "This Department is deeply concerned to have this law obeyed, and is prepared to enforce it, carrying cases into court when necessary."

Private Organizations

Although State and local authorities are responsible for enforcing health measures, the forces back of most State health legislation are the volunteer groups and private agencies. It was these groups that organized State societies for the prevention of blindness in newborn children; they all became active in preparing legislation to be enacted to prevent ophthalmia neonatorum.

The Illinois Society for Prevention of Blindness is an excellent example of this type of organization (14). In 1927, this society began its campaign for passage of legislation making it mandatory that a prophylaxis be instilled in the eyes of a newborn child. Audrey Hayden Gradle, executive secretary of the society, made a survey of the blind in Illinois, which showed that during the years 1921-30, in Chicago, 1,294 babies were hospitalized with ophthalmia neonatorum and 77 babies became blind as a result of this disease. Mrs. Gradle enlisted the sup-

port of many organizations: the Illinois State Medical Society, the State Board of Health, the Parent-Teacher Association, the women's clubs, Lions clubs, and the State Social Hygiene Association. Dr. William Snow of the American Social Hygiene Association assisted Mrs. Gradle by helping her organize standing committees and by making speeches throughout Illinois.

A bill for the prevention of ophthalmia neonatorum was drawn up with the assistance of the law department of Chicago University. It was fought bitterly by antimedical groups whose opposition to medical treatment was based on religious grounds and who flooded the legislature with protests. At that time, very few bills with social welfare implications survived the committee readings. (In Illinois, such bills must have three readings in both the House and the Senate committees and a favorable opinion by the attorney general before they are presented to the legislature for passage.)

An amendment to the bill, sponsored by the antimedical groups, was voted down 112 to 4. This amendment provided that if parents or guardians objected to the use of prophylaxis on grounds of religious beliefs, those persons would be exempt from the law. The original bill passed the Illinois Legislature and was sent to the Governor for his signature. The attorney general gave an adverse opinion that "police powers for the State did not cover the situation, and that individuals had certain fundamental rights which must be protected." Governor Emmerson vetoed the bill and it was sent back to the legislature.

On June 1, 1931, before the bill came up again in the legislature, the *Journal of the American Medical Association* carried a two-page editorial defending the bill. The Legislative Reference Bureau assured the Illinois Society for the Prevention of Blindness that the police power of Illinois was unlimited when loss of life and limb was concerned and that loss of eyesight ranked as equivalent to loss of life and limb. Helen Keller sent an open telegram to the legislature espousing the proposed legislation. Labor leaders wrote letters and lobbied for its passage, but the bill lost by six votes.

Mrs. Gradle did not give up the fight. She immediately began her campaign in prepara-

tion for the next session of the legislature. She went into the 51 legislative districts, organized committees in each district, made 350 speeches. She secured the support of leading obstetricians, who, at their own expense, testified before the Judiciary Committee. Mrs. Gradle kept 3,114 members of her standing committees working.

In January 1933 the bill was again introduced in the Illinois State Legislature. A new governor and a new attorney general were now in office. The bill was passed on April 18, 1933, and became effective on July 1, 1933. Under Illinois law, the enforcement of the provisions of the law became the duty of the State board of health.

A private agency such as the Illinois society has the advantage of "singleness of purpose," and acts as a catalyst. Other State societies for the prevention of blindness immediately began working on preventive legislation, emulating the courage and persistence of the workers in Illinois.

Constitutionality of Laws

The validity of the law requiring mandatory use of prophylaxis in the eyes of the newborn child and the reporting to the State health department of "inflammation of eyes" has been tested in court many times. In the case of *Medlin v. Bloom*, Massachusetts Supreme Court, 1918 (15), in an action of tort for defendant physician's negligence in caring for eyes of a newborn whereby the child becomes blind—whether defendant failed to treat the child's eyes with nitrate of silver or not after birth, and if not, whether the blindness was due to such omission as the proximate cause of the blindness—it was held to be a question for the jury to decide.

In this action the judge in the lower court instructed the jury, in substance, that "failure of the defendant to report the case ('inflamed eyes') to the State board of health as promptly as he should have done under RL 75 as amended by Statute 1905, chapter 251, section 2, was immaterial and was not to be considered as evidence of negligence." The lower court found for the defendant.

The Supreme Court of Massachusetts held that: "If you find the defendant violated the provisions of the act of 1905, that is evidence of negligence on part of the defendant." The court further held that "the evident purpose of the statute is that the board of health may be informed without delay of the existence of the most serious disease which may affect young children, so that immediate and scientific treatment may be received and blindness prevented. Such failure was evidence of neglect, and the decision of the lower court reversed and remanded."

In the case of *Dietsch v. Mayberry* (16), Ohio Appellate Court, 1942, it was held that the court is bound to take judicial notice of rules and regulations of the State board of health promulgated under statutes relating to investigation and report all cases of inflammation in the eyes of the newborn, under General Code, section 1248-1 to section 1248-5. The court held that the purpose of the statute is two-fold: (a) to benefit the newborn by preventing blindness, and (b) to relieve the public from the burden of supporting another blind child.

The court held that violation of such a statute was "negligence per se." The lower court found for the defendant but the Court of Appeals reversed the decision in favor of the plaintiff. This decision was based on the element of omission by the defendant in his duties to the plaintiff—his failure to notify the State board of health of the inflamed condition of the infant's eyes. This charge of negligence of the defendant had been omitted by the judge in the lower court in his general charges to the jury on negligence of defendant. Verdict was for the plaintiff, and the case was reversed and remanded.

Treatment

Since the discovery of penicillin, which is highly effective in the treatment of ophthalmia both locally and systemically, it has been shown that local ocular penicillin has prophylactic value. The proponents of silver nitrate prophylaxis opposed its abandonment in the treatment of ophthalmia neonatorum, although they admitted that a 1-percent solution of silver nitrate does cause chemical conjunctivitis

in a high percentage of cases. This condition is not serious, however, and there is no record of silver nitrate prophylaxis, properly performed, causing injury to an infant's eyes. The proponents of penicillin prophylaxis maintain that this antibiotic is equally efficacious in the prevention of ophthalmia neonatorum and has none of the objections leveled against silver nitrate.

The California State Board of Health amended its regulations pertaining to prophylaxis for ophthalmia neonatorum in June 1953 (17). The change provided for use of either 1 percent of silver nitrate in wax ampule or penicillin ointment. They accepted penicillin ointment as the only approved antibiotic preparation and recommended it on the basis of (a) data obtained from controlled clinical studies indicating its effectiveness and (b) ease of administration (18).

Summary

Ophthalmia neonatorum is a reportable disease and must be reported to the State health department in all States. In spite of the fact that the laws in all States require some prophylactic instillation in the eyes of the newborn child (which should prevent this infection), the disease still occurs. The table gives the number of cases of the disease in States which reported to the National Office of Vital Statistics in the years 1946-52. In 1952, only three States—Mississippi, Tennessee, and South Carolina—reported their ophthalmia neonatorum cases to the National Office of Vital Statistics.

Some form of prophylaxis against ophthalmia neonatorum is required by law or State board of health regulations in all States and in the District of Columbia. Thirty-three States require the use of prophylaxis for the prevention of this disease but leave the choice of prophylactic agent to the physician, the midwife, or the nurse in charge of the infant. All States require reporting of "inflamed eyes" occurring shortly after birth to the local health officer, who in turn must report the case to the State board of health.

Some States have qualified the use of prophylaxis for ophthalmia neonatorum; one State

requires ". . . if there is any reason to suspect an infection in the eyes of the newborn, then a prophylaxis must be applied." Another State qualifies the law by not requiring treatment for a minor child if the parent is a member of a recognized denomination whose religious convictions are against medical treatment. Another State provides that ". . . any parent shall not be required to employ such a prophylaxis (as required by State statute) if objections are

made in a written statement to physician or midwife in charge of the case.

The reduction of gonorrhea as a cause of blindness from 28 percent in 1908 to 1 percent in 1950 is a feat of preventive medicine of no small proportion. The continued role of gonorrhea in the production of blindness probably is attributable to errors in the method of use of prophylaxis rather than to ineffectiveness of the procedure itself.

The Salk Vaccine

The development and successful trial of the Salk vaccine against paralytic poliomyelitis is a major step toward control of a crippling disease. It represents the culmination of a truly historic medical and public health achievement.

This development of a successful vaccine places a great responsibility on the physicians, the public health agencies, and the parents in our Nation. I am confident that physicians and health officials

will conscientiously conserve and put to best use the supply of vaccine. Parents should cooperate with them. As the supply increases, there will be enough for all who wish to be immunized.

Within our time, therefore, we can expect to see effective control of crippling polio. I offer my sincere congratulations to all who have contributed to this great effort to protect future generations from the specter of poliomyelitis.

—LEONARD A. SCHEELE, Surgeon General,
Public Health Service, April 12, 1955.

Poliomyelitis Vaccination

The achievement of the new poliomyelitis vaccine is truly a great story deserving the full play it has received in the newspapers. It is one of the great public health events of the mid-century. It represents a triumph of basic research and an amazing example of effective teamwork.

The details of the evaluation of the 1954 field trial of the Salk vaccine, reported at the University of Michigan, April 12, have been adequately covered by the press. So I thought it would be more interesting to trace some of the scientific problems that had to be solved in the course of achieving a poliomyelitis vaccine and to attempt to outline some of the future developments and problems.

Until quite recently no coherent theory of the disease was established. The scientific basis for an effective means of immunization or control did not exist. Many facts were known, but they were separate pieces of a jigsaw puzzle that did not seem to fit together. For example, early epidemiological studies 50 years ago led to the inference that there were 100 persons infected for each one paralysed, but it was not until 1940 and later that this thesis was proved in the laboratory. The age distribution of cases, resembling that of measles, led to the inference that immunity followed an attack, but there were disconcerting numbers of bona fide instances of double attacks of the paralytic form of the disease. This cast doubt on the immunity mechanism.

Presented is a summary of Dr. Alexander D. Langmuir's informal remarks before the meeting of the Departmental Council of the Department of Health, Education, and Welfare, April 14, 1955. Dr. Langmuir is chief of the Epidemiology Branch, Communicable Disease Center, Public Health Service.

For many years it was believed that the virus had a peculiar predilection for nerve tissues. This belief led to the study of nasal sprays in an attempt to "block" the supposed pathway to the brain along the olfactory nerve. The treatment caused a lot of people temporarily to lose their sense of smell but did not prevent poliomyelitis.

Careful search for the virus in the blood failed to reveal its presence there with sufficient consistency to support the conclusion that blood was the mechanism for transfer of the virus to the brain.

In the laboratory for more than 30 years, the only animal susceptible to the infection was the monkey. In 1939, Dr. Charles A. Armstrong of the Public Health Service announced the isolation of the Lansing strain in mice, but this culture turned out to have so many peculiarities that some persons doubted for a time that it was truly a poliomyelitis virus. Tests for immunity to poliomyelitis viruses were very difficult, expensive, and often so inconsistent as to result in continued confusion.

In the field, epidemiological studies also left many points uncertain. The isolation of the virus from feces led many workers to think of the disease as comparable to typhoid. Later, the discovery of the virus in flies led to extensive attempts to control epidemics with DDT. The exact route of infection from one person to another remains in doubt, but increasing evidence points to the similarity of this infection to the other classical contagious diseases such as measles, chickenpox, and mumps.

In the solution of these problems, certain major "breaks" in the form of new discoveries and contributions to basic knowledge deserve special mention.

In 1948, Drs. Howard A. Howe, David Bodian, and Isabel M. Morgan, at Johns Hopkins University, were able to define the immu-

nity mechanisms in poliomyelitis by using large numbers of monkeys almost to the degree that other laboratories might use mice or guinea pigs. The availability of such numbers of monkeys was, of course, one of the brilliant contributions of the National Foundation for Infantile Paralysis. It was shown that three distinct types of poliomyelitis existed, each separate from the other. One of these types was the Lansing strain isolated by Dr. Armstrong. The existence of these three types adequately accounted for the occurrence of double attacks of the disease. A comparable experience is that one can catch German measles independently of true measles. The discovery of the three types of poliomyelitis and the existence of an immune mechanism similar to other diseases strongly suggested the possibility of a vaccine and indicated that all three types of virus would have to be included in it.

In 1949, Dr. John Enders at Harvard University announced the cultivation of the poliomyelitis virus in human tissue cultures. Later it was possible to grow the viruses abundantly in monkey tissues. This discovery made possible the production of the large quantities of virus, free of undesirable brain tissue, that would be necessary for a national supply of vaccine.

In 1951, when many workers were still thinking of poliomyelitis as primarily a disease of nerve tissues, Dr. David Bodian at Johns Hopkins and Dr. Dorothy M. Horstmann at Yale University simultaneously announced the discovery of the virus in the blood stream of monkeys and later of man. The key to this fundamental discovery was looking for the virus at the right time, namely, before symptoms developed rather than after the disease was in full swing. This discovery further gave promise of the probable effectiveness of a poliomyelitis vaccine because immunity in the blood would eliminate virus and probably prevent it reaching the nervous system.

In 1952, Dr. William Hammon at the University of Pittsburgh reported his successful studies of gamma globulin. These further supported the concept that a vaccine would be successful.

Thus, only in the last 3 to 4 years has a coherent theory of the disease been developed and

have the technological tools become available to permit in humans large-scale tests of vaccination against poliomyelitis.

In developing the actual vaccine, Dr. Jonas E. Salk of the University of Pittsburgh has been the extremely able executor of all this basic scientific development over many years in many laboratories. As he most aptly stated recently, "Dr. Enders threw a forward pass and I happened to catch it." He is an accomplished runner.

The Public Health Service is proud to have had the opportunity of participating in the vaccine evaluation by assigning Epidemic Intelligence Service officers to Dr. Thomas Francis' laboratory and to the collaborating States and research laboratories. They have been some of the soldiers on the team—doing much of the legwork in collecting basic records and specimens. They have contributed considerably to the accuracy and completeness of the data and thereby to the confidence in the conclusions that have been reported.

The Biologics Control Laboratory of the National Microbiological Institute, National Institutes of Health, worked closely with Dr. Salk and the participating pharmaceutical houses in developing standards for the vaccine. This laboratory, along with the NIH Rocky Mountain Laboratory at Hamilton, Mont., and the Virus Laboratory of the Communicable Disease Center, located in Montgomery, Ala., also participated in the vaccine evaluation.

I expect widespread acceptance of the vaccine this year. A rapid decline in the disease can be looked for. As yet it cannot be concluded whether the virus will disappear from the Nation or whether the infection will continue to spread among the population without causing paralysis in immune persons. If the infection progressively disappears, as I believe it will, then it will be necessary to immunize only a substantial number but not all susceptible persons in the population. If the virus continues to spread, then it will be necessary to exert particular effort to immunize 100 percent of the population, including adults. In either event, the supply of vaccine should become sufficient and the essential elimination of the paralytic form of the disease can be predicted with assurance.

Medical Librarianship

By ESTELLE BRODMAN, Ph.D.

JUST as there were nurses long before the profession of nursing came into formal being, so there were medical librarians before there was a profession of medical librarianship. As late as 1853, a meeting of American librarians in Philadelphia was attended not by librarians as such, but by clergymen, educators, some lawyers, and a few physicians, all of whom acted as librarians as well. Indeed, it might be said that librarianship as a profession did not begin to take shape until after the American Civil War, and medical librarianship, as differentiated from general librarianship, not until about the turn of the 20th century. Even then, when the Medical Library Association was founded, there were more physicians acting as librarians than there were professional librarians.

Today, medical libraries and medical librarians serve public health workers daily all over the country, especially by bringing them up-to-date information on the professional problems with which they are faced and by showing them how others have solved similar problems. Since medical libraries are one of the modern tools of the public health worker, a knowledge of their development and present status should be of interest.

In order to understand the late development

of medical librarianship, it is necessary to consider the conditions prevailing before the mid-19th century. For a profession to develop, there must be a large body of information available, a need for specialized techniques in handling the information, and a substantial number of people who need the information but do not have the time or inclination or ability for acquiring the specialized techniques.

Growth of Medical Literature

The first requirement for the development of medical librarianship was the existence of a large body of medical information. Medical literature has been accumulating for many centuries. Perhaps the earliest nonmagical medical works that have come down to us are the Egyptian papyri, the Papyrus Ebers and the Papyrus Edwin Smith, named after their modern discoverers but actually written about the 16th century B. C. from even earlier texts. The Papyrus Ebers is a medical treatise and the Papyrus Edwin Smith a surgical work (1), but both give such clear and accurate clinical descriptions as to leave no doubt of the high state of medicine at that time.

These papyri are not isolated examples of medical writings. There are copies of Indian medical works from the 7th to the 5th centuries B. C., the *Susruta*, the *Atreya*, and the *Vagbhata*, the first of which can be compared to the Papyrus Edwin Smith for its surgical cases and to modern works for scientific reasoning about such things as the relationship of mosquitoes to malaria and dead rats to plague.

Dr. Brodman is assistant librarian for reference services, Armed Forces Medical Library, Washington, D. C. She is also editor of the Bulletin of the Medical Library Association and author of the recent publication, Development of Medical Bibliography.

Chinese medicine also produced literature of a fairly high order somewhere between the 3d and 10th centuries B. C., and the writings of such Greek and Roman physicians as Hippocrates, Galen, and Celsus are known to all who have contact with medicine. Even during the so-called dark ages of Europe, medical literature was prepared, laboriously copied by hand, and circulated to interested persons, as shown by the books which we possess from that period: the writings of Constantinus Africanus, Roger of Palermo, Roland of Parma, Henri de Mondeville, and Guy de Chauliac, and the *Regimen Sanitatis Salernitanum*, among others.

Indexes to Medical Literature

With the invention of the printing press in the mid-15th century, the ability to reproduce books cheaply in large quantities led to an increase in the available literature in all fields, including medicine. It is a truism that physicians read medical literature primarily to learn what others have done in similar situations; it follows from this that the physician must be able to learn of the existence of writings bearing on his problem. As the printing press increased the medical works available to him, the physician found it increasingly difficult to learn about the existence of pertinent published information and to acquire it when aware of it.

As early as 1506, a new form of medical writing appeared, the list or bibliography of previous publications (2), to which the physician could refer when he wished to learn what had been written on a particular subject or by a particular person. The earliest printed medical bibliography, the *De Medicine Claris Scriptoribus* of Symphorien Champier, was followed by numerous other such lists, growing in size as the literature grew, and splitting into subdivisions by subject or by period of time, as the growing bulk of medical writings demanded.

Further intensifying the growth of medical literature was the emergence of the magazine or journal, which contained a number of contributions in each issue and which was meant to be continued indefinitely. The first medical magazine (periodical) was probably the *Acta medica* published in Copenhagen in the 17th century by the great Danish anatomist and physician,

Thomas Bartholin. The first medical journal printed in the vernacular was probably Nicolas de Blegny's *Nouvelles découvertes sur toutes les parties de la médecine*, begun in Paris in 1679. From these and from the pages of the transactions of the many learned societies which included medicine among the other sciences came such an increase in the literature that readers were swamped. It is estimated that today approximately 7,000 to 8,000 medical serials are published throughout the world.

The amount of medical literature available caused Wilhelm Gottfried Ploucquet, the German medicolegal expert and bibliographer, to complain bitterly of excess as early as 1808. "The job would be simpler," he said, "if the legacy were smaller, but the wealth of material overwhelms us, and we are blinded by too much light . . . To make matters worse, no day passes but someone throws another article on this mountain of material . . . Our life is too short, and there are so many books; money is so scarce, and there is so little time."

Specialized Techniques

The output of literature during the last few years of the 18th century began to be overwhelming, and the acceleration caused by the scientific discoveries of the mid- and late-19th century made a new approach to the problem imperative. In the 1860's, under the prodding of Joseph Henry, the first secretary of the Smithsonian Institution in Washington, D. C., the Royal Society of London began the collection and indexing of scientific literature, using groups of workers who were guided by a special committee of the society's members. The Royal Society Catalogue may be said to be the first large-scale joint venture into cooperative bibliography, and was a realistic attempt to meet a changed situation by adopting new methods to solve the problem. It has become the prototype of most of the bibliographic work done in the sciences since then. The most famous medical examples of this method are, of course, the *Index-Catalogue of the Library of the Surgeon-General's Office*, the *Quarterly Cumulative Index Medicus*, and the *Current List of Medical Literature*. Science bibliographers are now attempting to find still another

solution to the problem by the use of machines and newly developed storage devices.

This method of indexing the literature—bringing together a number of people to work jointly on a body of data—provided the second prerequisite for the growth of medical librarianship, specialized techniques. By the third quarter of the 19th century, medical literature had grown to such proportions that specialized techniques for handling it had to be devised. These techniques, in turn, required so much time to master and practice that physicians were unable to continue their previous work in the field. In addition, the amount of literature, which had made it more and more difficult for the private practitioner to afford to acquire or

house a medical library, had caused the proliferation of “public” medical libraries. Thus, the profession of medical librarianship began to come into being in the 1880’s and 1890’s and was so strong by 1898 that a Medical Library Association could be founded in that year.

Education for Medical Librarians

The development of medical libraries paralleled that of libraries in other fields. The American Library Association was founded in 1876, and the first school of librarianship started in 1887 at Columbia University in New York City. Eleven years later there were enough people engaged in the field of medical libraries to

Growth of periodical literature, 1800–1908.

make possible the organization of an association of medical librarians, and soon thereafter education for medical librarianship was discussed.

As the number of people engaged in library work grew, apprentice classes were held in large libraries and theoretical courses were given in colleges and universities to provide specialized education for librarians. Within these schools, a trend toward more courses, more hours of attendance, and more theoretical discussions gradually appeared. This trend was aided by the depression of the 1930's; since it was difficult to obtain jobs, more people were willing to lengthen their stay in school.

In the late 1920's and early 1930's, it began to be realized that not every kind of librarianship was exactly the same as every other kind. At first this led to library school classes based upon the group served by the library—college and university libraries, public libraries, or children's libraries. Later, the subject material handled became the criterion, and from a somewhat undifferentiated course on special libraries there sprang up courses on law librarianship, music librarianship, and medical librarianship. That this fractionation is likely to continue is shown by the fact that the Joint Committee on Library Education, set up by various American library associations, is investigating possible curriculums in still other portions of library work, such as journalism. On the other hand, a feeling has also arisen that there is indeed a core of study to which it would be well for all librarians to be exposed. In the late 1940's, many library schools in America revised their courses (and at the same time their scheme of degrees) to include the same core curriculum for all students. In the present setup, medical librarianship continues to be taught as an adjunct to the core curriculum.

Formal courses in medical librarianship began in the United States in 1937 and have continued to this time, thanks in part to the fact that this country was not disrupted by World War II as soon or as deeply as European countries. There have also been several attempts at education for medical librarians in other countries (3,4).

Since training in medical librarianship is a universal problem, the United Nations, through

its specialized agencies, the United Nations Educational, Scientific and Cultural Organization and the World Health Organization, has concerned itself with it. Workshops and courses for European medical librarians have been held or planned; traveling fellowships have been arranged to enable medical librarians from economically backward countries to visit medical libraries in other places; and the World Health Organization in the 1950's appointed the former head of its own library to visit medical libraries throughout Europe and give suggestions and whatever other aid was needed.

Medical Library Services

Since the training of medical librarians is based on the services they are expected to provide, it is profitable to consider what medical libraries offer. Public health workers are recipients of all these services. The most important part of any medical library is its collection; with a well-chosen stock of books, journals, and bibliographical indexes, the library will be of use to anyone truly seeking its information. The selection of materials is, therefore, a primary concern of the medical librarian, and the smaller the budget the more carefully must the selection be made. Once the collection has been brought together, the next step is preparing it for use by such devices as catalogs, classification systems, book markings, proper shelving, and the like. And, finally, the medical librarian helps the user through his knowledge of what is in his own collection and through his ability to obtain other material from outside collections. Occasionally, the librarian will make abstracts, reviews, or bibliographies for readers, though this is not common practice, and sometimes he will arrange for translations.

To prepare to perform these services, the medical librarian is ordinarily trained academically in colleges and schools of librarianship and by on-the-job internships. At present, there are more than 35 schools of librarianship in the United States which require a college degree for entrance. Students expecting to work in medical libraries usually present some academic scientific background before entering library school, though unfortunately not as many have this training as are needed. An-

other prerequisite for good work in a medical library is a knowledge of foreign languages, for, although it may be true that at present a large portion of medical research is reported in English, there is still a sizable amount in other languages. And the past literature, on which the present is based, contains perhaps 80 to 90 percent foreign material. The more German, French, Italian, or Russian a medical librarian can understand, therefore, the more valuable he will be.

The Medical Library Association has set up a voluntary certification program for medical librarians, which calls for college and library school training, with a special course in medical bibliography and librarianship, a course now given at three universities in the United States—at Columbia University in New York City, at Emory University in Emory University, Ga., and at the University of Southern California in Los Angeles. Scholarships are provided by the association to aid people taking these courses.

Present Status

Salaries offered medical librarians today generally start at around \$3,000 a year and tend to go up to about \$6,000, though heads of large medical libraries may receive as much as \$9,000–\$12,000. Since many medical libraries are connected with teaching institutions, the working conditions, vacations, pensions, and privileges tend to approach university standards. Normally about 60 new medical librarians can be absorbed each year, but the annual production of these specialized workers ranges around 30 a year. As a result, many nonspecialized librarians find their way into medical library work.

The number of medical libraries now in existence in the United States is not definitely known, but some 600 are members of the Medical Library Association, a professional organization international in scope but predominantly American in character. These include libraries in hospitals, medical schools, medical societies, nursing and dental schools, pharmaceutical libraries, psychiatric libraries, and at least eight libraries in departments of health. For membership in the association, a library

must maintain a collection of 1,000 or more medical and allied books of which at least 500 must have been published in the preceding 10 years; receive regularly a minimum of 25 journal titles appropriate to the institution; and have regular hours of opening and a regular attendant in charge.

The American Medical Association (5) and the American College of Surgeons (6) have also promulgated standards for libraries in the field of medicine; and the American Dental Association (7) and the National League of Nursing Education (8), for libraries in their fields, especially in hospitals approved by them for the training of interns and residents. The American Medical Association, the American College of Surgeons (9), the National League of Nursing Education (10, 11), and the Veterans Administration (12) have even gone so far as to publish lists of books and journals useful to such libraries, and the American College of Surgeons has even included hints on the administration of the collection (13). In the military field, the Office of the Surgeon General, United States Army, has long had a board for the review of medical books and journals, and it regularly publishes lists of officially "approved" books (14).

Although many guides and minimum standards have been established, the actual state of medical libraries in the United States varies enormously. Collections range from a few hundred out-of-date volumes and broken runs of journals to such mammoth libraries as the Armed Forces Medical Library, with its stock of close to 1 million titles, its receipt of over 4,000 periodicals, and its staff of over 200 people. The large majority of American medical libraries contain between 20,000 and 40,000 volumes, receive about 200 magazines regularly, spend approximately \$800 annually for other purchases, and have one or two professional librarians and a clerical worker on their staffs.

Future of Medical Librarianship

The major problems of medical librarianship today are these: (a) how to acquire, store, and make available the constantly enlarging body of literature being produced; (b) how to recruit and keep librarians trained in sciences,

child's life were also contributing positively to his better adjustment.

The Junior League again had first-hand contact with the field of mental health in 1948, when it was proposed that the group provide funds for psychiatric social work in a day care center. Such service, it was thought, could accomplish much for the children and their parents and might be extended to other local day care centers.

Investigation indicated, however, that the financial burden of the proposed project would be too heavy and that the community had more need for consolidation of services than for expansion of services. So the search continued for some feasible method of supplying psychiatric services in Holyoke.

In the winter of 1949-50, the league investigated possible new projects for which its children's fund could be used. Among the possibilities suggested was that of a mental health clinic for children, to be established in the local schools, and to be financed with State and local school funds. It was proposed that the league lay the foundation for getting the clinic under way and perhaps supply it with some financial and volunteer assistance when it was established. But it soon became clear that this project would require far more than league sponsorship.

In investigating the community's resources during this period, contact was made with the community organization expert of the Massachusetts State Department of Mental Health. His interest was to be of enduring usefulness since he not only met with the league members who were searching out possible projects, but he remained in constant touch with the group and was invaluable in encouraging and finally bringing the developing clinic to a successful culmination.

Together, the professional organization expert, the superintendent and assistant superintendent of the Holyoke schools, and the executive secretary of the Holyoke Community Council formed a small planning committee.

In line with the State mental health department's philosophy that "each community health program should serve an area with a population between 100,000 and 200,000," it was proposed

that the plan for the mental health clinic be extended beyond Holyoke to include Chicopee, Easthampton, Northampton, and South Hadley, Mass.

The Holyoke group was willing to accept this expansion of its original concept and to modify its plans from those of a local center to an area center. Representatives of the proposed area were invited to subsequent meetings of the planning committee. The pressing need for a clinic was voiced by all members of this new steering committee, which by now represented the fields of medicine, education, and social welfare.

Further exploration into the need for the clinic was then undertaken. Questionnaires were sent to physicians, schools, children's agencies, veterans groups, departments of public welfare, boards of health, and nursing associations. The replies pointed up the need for inservice training courses for professional personnel and for high quality in diagnosis and treatment.

Believing it worth while to explore the area's need even still more carefully, the steering committee met with top educators and local medical societies. Members of public and private social agencies, the city solicitor, and representatives of the probation department, women's clubs, and the clergy were present at one large meeting. Other meetings sought, in order to reach such groups as industry and the courts and labor organizations, to study the legal and economic aspects of the proposed mental health service. Various individuals brought to the meetings their point of view of the need and value to the community of enlightened psychiatric services.

A Major Setback

After these numerous meetings, formal application was made for Federal grant-in-aid. Unfortunately, owing to the demands of the Korean action, the application was not acted upon favorably, but encouragement was held out for the future.

It is evidence of the strength of the structure erected by the steering committee that this setback in its carefully documented plan did not cause it to disintegrate or to turn to other, less

frustrating projects. It is evidence, too, of the wisdom of bringing into the planning representatives of many fields whose practical needs now encouraged the league to sustain its interest in spite of the serious reverse.

The Holyoke Junior League showed some interest in reverting to the original plan of providing a service for Holyoke alone, and there was some exploration of the possibility of organizing a small clinic as part of the Holyoke Hospital's outpatient service. But these suggestions only served to strengthen the conclusion that a clinic must spread its influence into the community and that there was need among the community's professional workers for psychiatric consultation. It was believed that a very small clinic with its necessarily limited caseload would not have enough effect on the community if the only contact of the staff with the community were a direct one with the patients.

In the year 1951-52, when the prospects for the original plan to establish mental health services for Holyoke seemed to be even more obscure than ever, much progress was actually being made.

It might even be postulated that the long period of preparation for the clinic and the unwavering interest in realization of the project, in spite of the many setbacks, were major factors in assuring ultimate success.

Increasingly, the continuing members of the steering committee, meeting informally, came to see their project in much the same light as the whole problem of mental health service was being appraised nationally—not as the establishment of a treatment clinic alone, but as a focus for mental health activity through an entire area.

They began to think in terms not only of providing psychiatric outpatient care for the many individuals in the community who were in need of such help but of a long-range and fluid program for improving the mental health of the whole area.

Help From the State

The State department of mental health, in making its survey of the services then available in the State in order to determine the

direction of its own future growth, based its thinking on a philosophy of prevention of mental ills. In planning for new clinical facilities, the department considered as a prime requisite the readiness of the community to accept such concepts.

The department expressed the philosophy of its mental health program in the *Mental Health News Letter* of the Massachusetts Association for Mental Health (June-July 1953):

"The State will join with any responsible and representative community group to work towards bringing to the community a mental health and psychiatric clinic program. By responsible we mean that the community group must be dedicated to the continuing job of mental health promotion in the community. It must be able to provide funds on an annual basis from an annual drive, community chest, or other sources. It must be able to write checks, employ personnel, and provide quarters, equipment, and supplies. It has to take a very active part in mental health education, interpreting the function of the mental health program to the community. Furthermore, it must interpret community needs to the professional staff and help it in formulating policies concerning the overall operation of the mental health program."

The department of mental health recognized that although the steering committee had no formal organization it met the requirement of being a responsible and representative group. Consequently, when its survey corroborated the need for psychiatric services in the Holyoke area, the department chose to place a new community clinic there.

Notice came to the steering committee in September 1952 that funds would be immediately available from the department for the establishment of professional psychiatric services.

The committee called a number of meetings to form an association which would assist the State department of mental health by providing clinic space, secretarial service, and maintenance funds. The department made it clear that it would cooperate, as closely as consistent with good professional practice, in carrying out the policies of the association as they represented community needs.

All of the areas that had shown an interest in the formation of the original clinic were now organized under the name of the Mental Health Association of Holyoke, Chicopee and Northampton Area, Inc. A constitution and bylaws were adopted; a board of directors and officers were elected; and application for incorporation was made.

An advisory committee, representative of all the communities and of medicine, education, nursing, social welfare, and the clergy, was formed. One of its early functions was the determination of admission and fee policies. Later, it made known to the clinic some of the problems of local physicians and attempted to find some solutions. This committee has continued to meet, advising on community needs and attitudes.

One of the first responsibilities faced by the board of directors was the raising of funds to cover rent and secretarial and general office expense, and to purchase office equipment. The estimated association budget for the first 18 months of operation was \$10,000; professional salaries were met by the State.

With these funds in hand, it was possible to secure sufficient personnel to provide some professional service by November 15, 1952. The clinic opened as a community health service on February 8, 1953. Treatment was offered for children and their families; consultation was available to physicians and other professional groups in the area; and a program of mental health education was begun.

From the start, the clinic was open 5 days a week, 8½ hours a day, from 8:45 a. m. to 5:15 p. m. The staff consisted of a full-time psychiatrist, a psychologist, a psychiatric social worker, and a secretary.

In July 1954, when a need for the expansion of services was already being demonstrated, the association asked the State department of mental health for more staff. At the same time, it agreed to provide the additional office space and secretarial help. The department was able to provide a clinical psychologist for the newly created departmental position of mental health consultant. His main function was to work with the schools of the area. When it appeared that the department could not provide the part-

time social worker the association had also requested, the association itself took on this responsibility.

At first, housing the clinic was a serious problem, for the clinic operated in rooms donated by the school department, in the beginning in the basement of a school, then in the empty classrooms of an abandoned schoolhouse. Rooms were eventually found in a centrally located office building, and additional space was leased as the clinic's needs increased. In its present location, the clinic is accessible to the whole area it serves; it is no more than a half hour away from any part of the communities.

Each participating community was given an estimate of its share in the budget, arrived at through a rough estimate of population, and was asked to raise the amount in its own way. Care was taken that the association representatives in the communities thoroughly understood the clinic functions, and in the consequent appeal letters and newspaper stories used for money-raising purposes the interpretation of the clinic's work was emphasized.

The success of the funds-raising project varied in the communities although the sum needed was collected. In attempting an informal analysis of reasons for this variation, some felt that one difficulty arose because the incorporation of the clinic was not completed before the drive began. If this had been foreseen, the incorporation papers could have been obtained in an earlier planning phase.

The Clinic in Operation

The present staff consists of a full-time psychiatrist, who is the director of the clinic, a psychologist, the mental health consultant, a full-time head psychiatric social worker, a part-time social worker, and two secretaries, one full-time and one part-time. It is believed that this staff will serve to meet the clinic's needs for the next few years and that the same pattern of a joint undertaking between the association and the department of mental health will continue to apply when further expansion becomes necessary. The present annual budget of the association is \$9,950, and that of the State department of mental health is \$19,900.

No exact formula for dividing the financial responsibility is in existence, nor is this envisaged. Rather, the concept of responsibility is one of joint planning and participation within the capabilities of the State group and the local group.

The communities plan to raise their share of the association funds through the community chest or as part of the school budget and public health funds. There is still some individual solicitation, but it is planned to have this kept at a minimum in the future with the stress on community support of a community agency whose presence is of value both directly and indirectly. Plans are being worked out for social agencies to pay for the consultant services available, and some are already doing so on a retainer rather than on an hourly fee basis.

The clinic accepts for treatment children between the ages of 2 and 18. While no formal

statement is made as to eligibility, it is understood by the staff that there must be some selection of cases in order to function at all adequately. Therefore, the emphasis in selection is on the type of emotional disturbance which can be expected to improve with intensive (weekly) treatment over 6 months to 1 year.

Since the philosophy of the clinic is based on the premise that part of clinical responsibility lies in the field of prevention, consultation work is done regularly or on a request basis with teachers, social agency personnel, the courts, and the clergy.

The acceptance and widening use of the consultation service would indicate that this is an additional service toward meeting the demands of the community and helping those who work with children to understand them better and to improve the mental health climate for all children in the entire area.

The Dug Well— Sanitary Aspects

35 mm. filmstrip, sound, color, 10 minutes, 72 frames. 1954.

Audience: Sanitary engineers, sanitarians, public health inspectors, and others interested in water supplies.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

Public health aspects of dug wells are portrayed in this filmstrip. Em-

phasis is placed on site selection for a well and on construction principles, methods, and materials to be used to best advantage for the location. Types of pumps are demonstrated and the proper installation of each explained. Water sampling and disinfecting techniques are included in the study.

A Large Water Treatment Plant

35 mm. filmstrip, sound, color, 12 minutes, 84 frames. 1954.

Audience: Sanitarians, sanitary engineers and trainees, and others interested in modern water treatment plants.

Available: Loan—Public Health Service, Communicable Disease Center, 50 7th St., NE., Atlanta 5, Ga. Purchase—United World Films, Inc., 1445 Park Ave., New York 29, N. Y.

Designed to be shown in lieu of making a field trip or to supplement a field trip, the filmstrip shows the equipment of a large modern water treatment plant. It takes the viewer through the plant, beginning with the raw water and intake facilities and structures and following through the chemical treatment, coagulation and settling processes, and the filtering

Adjusting a chlorinator.

Panoramic view of a trickling filter plant.

and chlorinating operations. The corrosion control equipment is also pictured.

Pit privy is source of pollution to dug well.

Hospital Beds

in the United States, 1955

By LESLIE MORGAN ABBE, B.S.

THE COMPREHENSIVE, long-range plans for hospital facilities developed in connection with Title VI of the Public Health Service Act are revised annually. This continuing responsibility of the official State hospital planning agencies has come, with ripening experience, to provide an authoritative sourcebook on the Nation's hospital resources. Both total capacities and highlights of operating data are recorded in these annual tabulations. By "capacity" is meant that capacity

for which the hospital was planned, rather than a fluctuating bed count, which may reflect either a serious overcrowding or a closed wing. Also, beds which are unacceptable because of functional or physical hazards are listed separately from the acceptable capacity.

Table 1 shows on this basis the record of existing hospital beds in each State and Territory as of January 1, 1955, according to the four principal categories of service provided: general, mental, chronic, and tuberculosis. States are grouped, for convenience of comparison, by the broad socioeconomic regions of the United States.

We now have approximately 1,100,000 acceptable beds in all four categories, with 176,000 additional beds which were classified by the

Mr. Abbe is assistant chief of the Program Evaluation and Reports Branch, Division of Hospital Facilities, Public Health Service.

This current inventory and continuation report brings up to date the general review of hospital bed requirements in the United States, published in *Public Health Reports*, April 1953, p. 425. It also outlines the present situation in other types of medical facilities and pending efforts for their expansion. The report is limited to hospital bed needs and related accomplishments in that field, including the Hospital Survey and Construction (Hill-Burton) Program. It does not cover nursing home beds and other fields of accomplishment such as the construction of public health centers, State health laboratories, and related health facilities.

State agencies as nonacceptable for long-range use. Nearly one-half of these acceptable beds, 526,000, are in general hospitals, and mental hospitals have 40 percent of the total. The record of nonacceptable beds is undergoing continual change, as closer inspections identify other obsolete and hazardous conditions. New construction, on the other hand, is replacing and removing from the record a considerable number of such outmoded facilities.

The data in table 1 do not include beds for civilians in Federal hospitals. In general, these do not provide communitywide service available to the general public. According to recent reports, there are 117,000 such beds in operation in veterans hospitals and about 8,000 more in hospitals operated by the Public Health Service for merchant seamen and others, including some Indian facilities.

What Has Happened Lately

During World War II, hospital construction was virtually at a standstill. After 1946, accumulated reserves of public and private funds were applied to meet long-deferred needs. The encouragement of Federal assistance under the Federal Hospital Survey and Construction Act of 1946 combined to establish an unprecedented peak in hospital construction volume.

Figure 1 shows the history of hospital construction from 1920 to date, at constant prices, and in relation to a growing population. This chart indicates that the postwar peak volume of construction in 1950 amounted to \$5.00 per capita as compared with \$1.00 per capita, or less, during 1942-44 and as compared with a previous high point in 1929 of about \$3.50 per capita, at constant prices. If the volume of

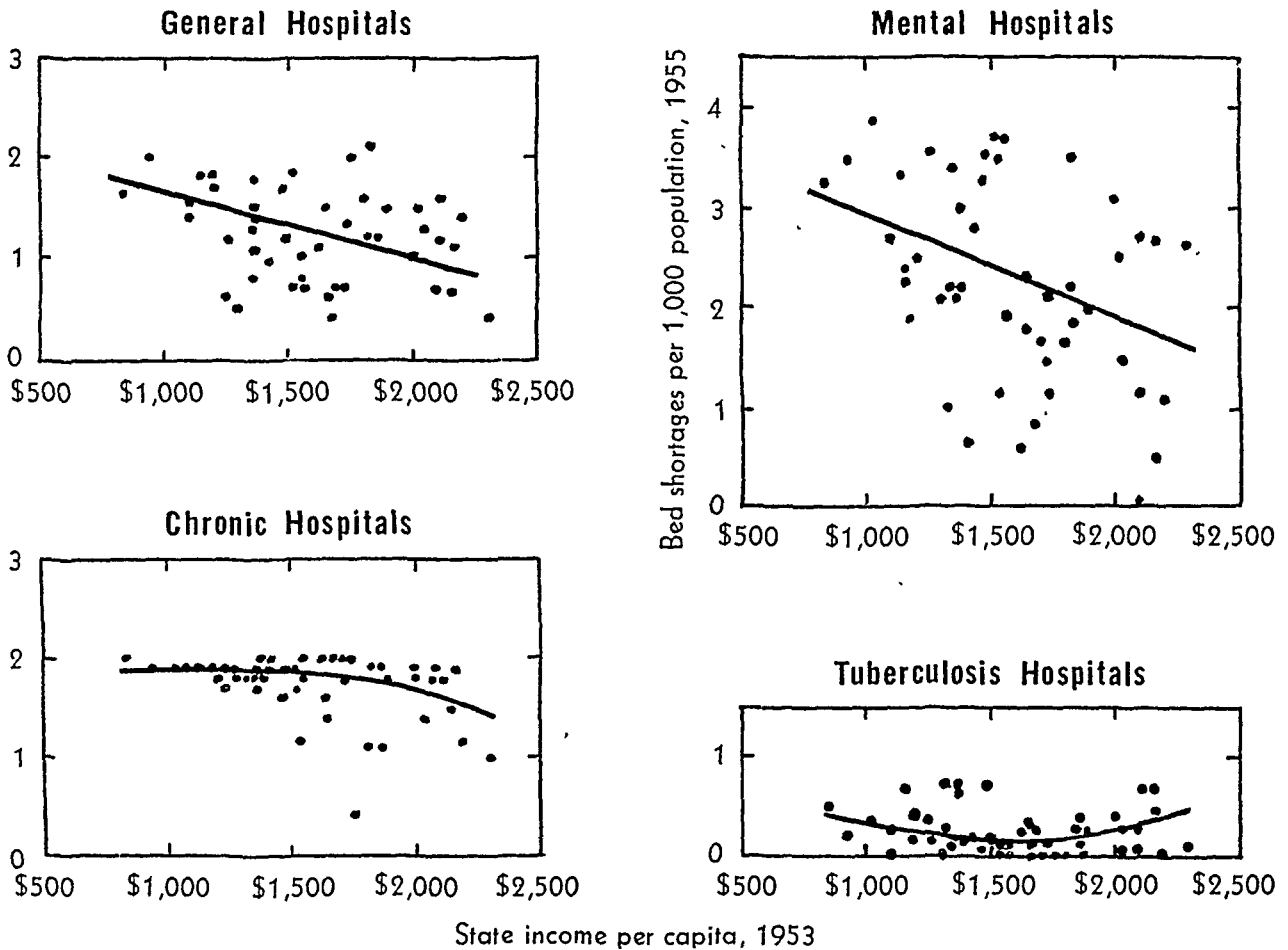

direct Federal construction and federally aided construction is excluded, the remainder undertaken entirely by State and local resources is somewhat less than the 1929 volume per capita—or less than \$3.00. It will be seen that relative volume has declined sharply from the postwar peak.

Studies on the regional distribution of the recent volume of hospital construction (1) show that the largest total activity per capita is occurring in the high-income census regions of the Nation. Federally aided construction accounts for nearly all new work in the regions of lowest income, while in the region of highest income federally aided construction is a minor portion of total construction activity.

The annual log of the State hospital plans, from its beginning in 1948, helps to put this construction history in perspective. It reflects the net gains from new construction, against mounting obsolescence and rapid growth in population. In addition to inventories, these plans show the remaining need in each category of hospital, according to standards prescribed by the basic act and regulations thereunder.

The annual summary of beds and additional needs from 1948 to 1955 is contained in table 2. This record shows that there are today nearly 260,000 more hospital beds in the country than in 1948; of this number, 220,000 are acceptable beds. On the other hand, 27,000 more non-acceptable beds are recorded. The net progress in reducing the total backlog of need has been limited, amounting to about 70,000 beds, or less than 8 percent. Nationally, our general hospitals now have 73 percent of total requirements, while mental hospitals have only 56 percent of requirements, and chronic hospitals

Figure 3. Principal hospital categories show widely different patterns of shortages in relation to State income.

vide for the care of acute and long-term illness, under direct medical attention. However, skilled care, not requiring hospital resources, may be provided under medical supervision in nursing and convalescent homes. Diagnostic and treatment centers for ambulatory patients can do much to lessen the duration and effect of illness. Rehabilitation centers are another important form of health facility needed to restore disabled persons to the maximum degree of self-sufficiency. Total needs in these types of facilities and the existing plant are still unknown. A recent national survey of nursing homes (2) shows that there are now about 200,000 beds with skilled nursing care in such facilities.

The program of Federal assistance for hospital construction was broadened by 1954 amendments to the Public Health Service Act

to include additional assistance for facilities providing long-term care (either in chronic hospitals or in nursing homes), for diagnostic or treatment centers for ambulatory patients, and for comprehensive facilities for the disabled. Statewide inventories are still in process from which State plans will be developed for a construction program relating to these types of facilities.

Summary

New hospital construction has been substantial throughout the postwar era.

Net gain in relation to total bed need has been considerable for general hospitals; additions to mental hospitals have not kept pace with population growth and obsolescence.

Statewide remaining bed need is unevenly

distributed and tends to be substantially higher in low-income States, with total construction volume smaller in low-income regions than in regions of highest income.

Growing attention is being given to related health facilities besides hospitals, in order to round out comprehensive health services.

Experience is maturing on broad planning for hospital bed needs, but need for other types

of medical facilities has just begun to be appraised systematically.

How Charleston County Uses a Staff Newsletter

By GERALD J. SPECTER, M.P.H.

NEW AND VIEWS, the staff newsletter of the Charleston County (S. C.) Health Department, made its first appearance in December 1952. Since then, 30 issues have come off the press.

The idea of a house organ is not new. Nor is the use to which a house organ was put in our health department any different from what you would ordinarily expect to find. The value in using a departmental publication can only be measured by asking, "Does it accomplish what it has set out to do?"

Two years ago, there was a noticeable lack of communication among staff members and divisions in this health department. Each employee was busily engaged in performing his own particular job. Each division was principally concerned with its own objectives rather than with those of the overall department program. Each division saw health problems only in its own light.

Perhaps this atmosphere was partly due to a lack of understanding of each member's place on the health department team and of how one staff member could supplement the work of another. Could this be the situation?

What aid could the sanitarian be to the public health nurse in the district?

How did the laboratory staff fit into the picture?

Mr. Specter, public health educator, Charleston County Health Department, Charleston, S. C., since 1952, is also executive secretary for the Charleston County Safety Council and for the Charleston County Health Council. He was with the Pittsburgh City Health Department in 1949 and 1951 as a sanitarian.

What kept the statistical clerks, the clinic personnel, the laboratory technicians, and some of the lesser known workers so very busy?

What were we all doing?

For example: What were the sanitarians doing in connection with the county's new program of regulating subdivisions? What were the public health nurses doing to improve the rate of diphtheria immunization? What was the health council doing about dental health education in the public schools?

These were some of the questions that we thought needed answering if the "oneness" of team approach was to be achieved in our county. This problem of staff communication became the main topic of discussion at a meeting of the health officer and division supervisors, where it was unanimously decided to undertake to educate each staff member about the position on the team assigned to his teammates.

Many suggestions were offered. One was to hold staff seminars. Another proposed inservice training for each division, using these sessions for outlining the functions of all other divisions. A third suggestion was to have some method of keeping staff members informed and up to date on what was happening within the entire department.

The idea of circulating a monthly health department newsletter was broached to the staff. Each division would be asked to contribute information that would answer many of the questions staff members might have about other health jobs within the program. Staff members would also be invited to contribute personal items to give the newsletter an informal touch.

News, Views, and Information

A poll of the entire staff told us that a newsletter would be received with enthusiasm, and plans were made to get into print as soon as possible.

No attempt was made to make *News and Views* a journalistic masterpiece. Its tone is informal, yet distinctive.

Early issues featured news about the activities of the various divisions.

The news is not confined to health department happenings specifically—mention is made of extracurricular activities. Articles of special public health interest to the staff are also used. A special section in each issue is devoted to birthday greetings and mention of service records. Special stories cite honors received by employees.

As time went by, we received more news items than we could possibly use in a single issue. When this happened, we enlarged our newsletter from the original one sheet to double this size.

In format, *News and Views* is mimeographed on 8½-inch by 11-inch paper. Each page is typed in two columns. Items are kept brief, personal, and informal. There is no set space restriction. Only the amount of news received determines how many pages an issue will contain.

The early runs numbered 75 copies until requests for the newsletter from outside the county department began to come in. The circulation list has been expanded to include staff members of the South Carolina State Board of Health, members of our own board of health, members of the county council, the legislative delegates from our district and members of their staff, former employees of our department, local voluntary health agencies, and many others. Circulation now exceeds 250 copies.

A brief estimate of costs for a 4-side, 2-page issue, follows:

<i>Supplies</i>	<i>Cost</i>
4 stencils ¹ -----	\$0.60
½ ream paper-----	.55
Ink (approximate)-----	.25
2d class postage-----	2.00
1st class postage-----	1.50
Envelopes -----	.80

Total cost for printing and mailing ²----- \$5.70

¹ The masthead page can be produced in larger quantities in advance.

² 40 percent of distribution made in building where health department and other agency offices are located.

After 25 issues of the newsletter, in July 1954, we asked our 68 staff members to help us evaluate *News and Views*. Their answers to a

questionnaire provided a small study to help us determine whether the letter was accomplishing what it had set out to do.

The Evaluation

The first inquiry dealt with the extent to which each staff member read the house organ—

80 percent said they read *News and Views* thoroughly.

5 percent answered that it was only partly read.

15 percent did not comment.

We next asked how well do most items interest the reader—

75 percent answered that most items were of interest to them.

10 percent indicated fair interest.

15 percent had no opinion.

Another question asked whether *News and Views* has helped the individual to know more about health department activities other than his own—

75 percent answered that it has helped.

10 percent answered that it has helped somewhat.

15 percent had no comment.

We also wanted to know to what degree, as a result of reading the newsletter, the reader became familiar with the overall program of the health department—

67 percent replied, "Very much more."

25 percent stated that they were only a little more familiar with the overall program.

3 percent said their awareness was the same as before.

5 percent did not comment.

Next, we asked whether *News and Views* helped clarify an individual's understanding of the health department's program by familiarizing him with the work of the various divisions—

70 percent indicated that it had accomplished this purpose.

5 percent indicated that it had not.

10 percent were undecided.

15 percent had no comment.

When we asked whether a newsletter such as ours helps cement relationships among staff personnel, we received a more divided reply—

58 percent thought the relationship was much improved.

32 percent felt relationships had improved a little.

10 percent had no opinion.

We then asked, "Do you think having a newsletter has been worth while?" To this—

85 percent answered, "Very much so."

5 percent said such newsletter was all right.

10 percent made no comment.

No one answered that *News and Views* was not worth while.

Our final question asked whether each staff member was satisfied with *News and Views* as it now stands—

85 percent replied they were satisfied.

5 percent believed some changes were in order.

10 percent did not comment on this question.

From their answers, the staff seems to think *News and Views* has helped to bring each individual closer to one another. It has helped, we believe, to contribute to the feeling of "oneness," so very much needed and has given direction and insight to the team approach.

We realize that a staff newsletter is not the complete answer, but from all indications, it seems to be a start in the right direction. Other steps being undertaken are joint planning, regularly scheduled general staff conferences, inservice training programs, and free exchange of ideas. There is no single panacea, but we hope all these efforts will produce results.

An Important Date

Each month your health department and many hospitals, laboratories, schools, clinics, and homes receive a copy of PUBLIC HEALTH REPORTS, mailed to arrive on the 20th, or even earlier, depending upon geographic location of the subscriber.

Its pages carry timely research reports, analyses of current trends, new methods, concepts, and ideas, and topical reviews for the busy scientist, teacher, or public health worker. Capsule coverage of important public health meetings, like those of the American Public Health Association, help the PHR reader.

Not all our readers receive the journal on the delivery date. An official copy is trickled down to them through a series of other readers. Sometimes the trickle slows to a complete halt.

You can have your personal copy promptly. Use the subscription blank on the inside back cover. Let the 20th of each month be an important date for you, too.

Questions about the cause, the effect, the diagnosis, the infectivity, the clinical pattern, the prevention, and the treatment of trachoma are answered by an ophthalmologist from his experience and from the literature.

The Trachoma Story

By ARTHUR A. SINISCAL, M.D.

THE IMPORTANCE of trachoma "as a source of human suffering, as a cause of blindness, and as a national economic loss over large tracts of the world's surface is second to none among the diseases of the eye, or indeed, among diseases of all kinds."

Thus Sir Stewart Duke-Elder, a distinguished British ophthalmologist, assessed trachoma in a textbook published in 1934 (1). As late as 1950, it was estimated that 15 to 20 percent of the world population suffered from this disease (2).

Throughout the world, trachomatologists, ophthalmologists, sociologists, public health workers, and others are striving earnestly to improve the health and socioeconomic conditions of those afflicted with trachoma. But they have no magic wand; what they accomplish, they accomplish through steady, organized effort, which depends in turn upon public understanding and support. The following pages tell of medicine's planned attack against this ancient infection.

According to Moutinho (3), trachoma was

Dr. Siniscal since 1944 has been medical director of the Missouri Trachoma Hospital in Rolla, a service of the division of health, Missouri Department of Public Health and Welfare.

well known in the civilizations of the four great river valleys—the Hwang Ho and the Yangtze Kiang, the Indus and Ganges, the Euphrates and Tigris, and the Nile—many centuries before Christ. It was recognized and treated in ancient Egypt, Greece, and Rome, as well as in countries of Biblical fame. The Moslem conquests probably led to its spread to Europe as early as the eighth century (4), and, undoubtedly, Napoleon's campaign to Egypt in 1798–1802 was responsible in large measure for its dispersion among the Europeans (5).

Believed to have been introduced into the United States during colonial times by European immigrants (6), the disease was spread throughout a central belt reaching from the Allegheny Mountains to Kansas and Oklahoma, among the Indians as well as others. According to Cosgrove (7), the trachoma found in Missouri and Arkansas originated from persons who came into these States from Tennessee and Kentucky. The trachoma in New Mexico and Arizona and probably California is believed to have come from Mexico (8).

Today, trachoma is found on every continent (4). It is common in most of Asia, where it affects from 30 to 60 percent of the population. It is somewhat common in Europe, where it affects approximately 5 percent of the population. More prevalent in the Balkan States and in northern European countries than elsewhere on

that continent, it is present also in France, the Netherlands, Germany, Austria, Hungary, Italy, Ireland, Great Britain, Norway, Sweden, and Denmark.

Once a serious public health problem in the United States, particularly in the central portion where it is considered endemic, trachoma is now relatively rare. It is still present, however, in Missouri and Arkansas and, to a lesser extent, in southern Illinois. In Missouri, active cases are found in the southern half of the State, particularly in the cotton-growing lowlands and in remote regions of the Ozark hill country. Accounting for 1 out of 4 pensioners on the State's blind pension roll 25 years ago, trachoma now is the disease of only 1 out of every 10 blind pensioners.

Questions asked most frequently about trachoma are given here with the answers available from the experience of many workers. Although much is known about the cause, the diagnosis, the clinical manifestations, and the prevention and treatment of this disease, not every question can yet be answered finally or completely.

What Is Trachoma?

Trachoma is an infectious disease of the external lining membranes (or conjunctiva) of the eyeball and eyelids. It causes an inflammation of chronic duration, characterized by burning, itching, excessive lacrimation, and photophobia. Generally insidious in onset, it develops usually at a slow pace and is somewhat resistant to treatment. The disease is localized strictly to the conjunctiva of the eyelids and eyeball and to the tarsus and the cornea. The pathological changes in the tarsus and the cornea are deep seated and usually irreversible when once established. Persistent duration of inflammatory symptoms may lead to blindness, which results from corneal opacification and disintegration and, further, from cicatrized deformities of the eyelids and eyeball.

What Is the Cause of Trachoma?

The etiological agent is believed to be a large virus or inclusion body of the group which includes the psittacosis and lymphogranuloma venereum viruses. The inclusion body of

trachoma is indistinguishable morphologically from that of the virus causing inclusion blennorrhea of infants and swimming pool conjunctivitis of adults (also called paratrachoma). Some workers have regarded the agents of these infections as belonging to the *Rickettsia* group, but Bengtson's (9) research has shown that the trachoma bodies are rather distinct from the rickettsiae. Generally speaking, the view is taken that the trachoma body is a virus, but the question has not yet been finally settled. The dividing line between bacteria and rickettsiae or between rickettsiae and viruses is not sharp.

A great majority of scientists now believe that trachoma is due to the organism discovered by Prowazek and Halberstaedter. In 1907, they described cytoplasmic inclusions, the presence of which in the epithelial cells of the conjunctiva and the cornea manifests the first detectable sign of the disease in the laboratory. Thygeson (10) has pointed out that these intracellular parasites are relatively large particles and that their life cycle is very similar to that of the psittacosis and lymphogranuloma venereum viruses.

There is need for more research on the causative agent or agents of trachoma. The exact nature of the organism will remain obscure until it is definitely isolated and successfully cultivated.

How Are the Eyes and Eyesight Affected?

If the infection is allowed to progress without treatment for several months or longer, a lymphoid infiltration in the conjunctiva and in the subepithelial tissue will result in hypertrophy and thickening of the conjunctiva and eventually in connective tissue formation and scarring. Even the tarsal plates are involved and may become buckled or deformed as a result of cicatrization. Follicles may or may not develop, but the absence of these should not rule out the presence of the disease (11, 12).

The most serious pathological complication of trachoma is considered to be the formation of pannus, which is a vascular invasion under the epithelium of the cornea. When pannus is allowed to progress centrally, the pupil becomes obscured by this veil-like opacity. Trichiasis,

Florid pannus covering complete upper half of cornea, as seen in advanced stage of trachoma. Pannus is pathognomonic of the disease.

cicatrization of corneal follicles; (c) finding of the inclusion bodies.

A study by Rice and Smith (17) of the records for 1,154 cases of trachoma found that 88 percent showed the presence of pannus involvement of the cornea. According to Cosgrove (7), a definite diagnosis of trachoma cannot be made without pannus unless a proved case has been seen in the same family. Recently, however, Julianelle and Smith (18) observed that approximately 37 percent of early trachoma cases do not show any pannus, and Mitsui (19) states that even a microscopic pannus can be absent in the earliest stage in some cases of trachoma. Mitsui observes that in Japan, microscopic pannus can be seen in about 50 percent of trachoma cases during the acute stage, and that marginal punctate infiltration of the cornea can be seen in a smaller percentage of cases.

Cuenod and Nataf (20), who stress the value of slit-lamp biomicroscopy in their monograph on corneal studies (21), state that pannus is one of the most constant pathological signs of trachoma, but that they believe it possible for true trachoma to occur without pannus, especially

a condition of ingrowing eyelashes, results from cicatrization of the lid structures; it causes the eyelashes to rub against the cornea, thereby destroying the epithelium and predisposing to ulceration, perforation, and dense corneal scarring. Blindness may be due to diffuse corneal scars in general, or to pannus formation over the pupillary area, or occasionally to secondary uveitis following perforation of the chamber and prolapse of its contents, resulting eventually in phthisis bulbi.

Is Pannus Essential to the Diagnosis?

Although the presence of typical trachomatous pannus is a solid basis for making a diagnosis of trachoma, its absence does not absolutely rule out the diagnosis. Some observers (13-16) believe that any one or more of the following signs should be sufficient to establish a diagnosis of trachoma: (a) presence of typical follicles; (b) presence of pannus; (c) presence of cicatrization; (d) punctate depressions at the periphery of the cornea resulting from

Trachoma granules in the conjunctiva, as seen in the florid stage of the disease.

the early stage. Nataf (22) states further that, in his opinion, it is possible for certain forms of the infection to occur without pannus but that diagnosis in such cases should be made with reservations. Nataf believes that trachoma may possibly occur in certain regions without pannus, but that in order to prove diagnosis in such cases it would be necessary to detect, after regression, the typical scarring pathognomonic of trachoma.

Why Is Early Diagnosis Important?

As in other infectious diseases, early diagnosis and treatment of trachoma prevent its spread. Early discovery also makes it possible to prevent the advanced stages with their irreversible complications.

A clinical diagnosis of trachoma in its early stage is always difficult, since the classical landmarks of pannus, corneal infiltration, mature follicles, or cicatrization may not be present. The lack of agreement as to a definite differential diagnosis of early trachoma makes necessary a laboratory confirmation of the diagnosis whenever possible. However, because the virus is difficult to isolate or cultivate, a negative laboratory finding is unreliable.

Although the presence of inclusion bodies may clinch a positive diagnosis, their absence does not necessarily verify a negative diagnosis. The reason for this is that microbiotic or cellular findings typical of trachoma infection are not present throughout the length of the disease; it may be possible to find positive material from conjunctival scrapings early in the disease, but not always. In this connection a serologic test would be helpful. There is a clear-cut need for research on the serology and immunology of this disease.

The presence of several or all of the following signs plus a history of contact should make one strongly suspect that the diagnosis is early trachoma: excessive lacrimation with photophobia; papillary hypertrophy of the palpebral conjunctiva; a peculiar haziness of the lower cul-de-sac indicating diffuse infiltration therein; swelling and decreased rigidity of the upper tarsus; tiny filamentous symblephara in the upper fornices; large, discrete follicles; incipient pannus; and upper corneal infiltration. These signs may

occur in other conjunctival diseases, but in an endemic area of trachoma, one would be remiss in his duties if he neglected to take cognizance of them.

Lindner (5) states that in areas where trachoma is prevalent, every case of slight, ordinary conjunctivitis may be beginning trachoma. He considers the most important sign of the first stage to be the peculiar haziness of the conjunctiva of the lower cul-de-sac. Kuo (23) also stresses the importance of general haziness of the lower cul-de-sac, together with incipient pannus, in making an early diagnosis. Tabone (24) discovered that in a series of cases of eye infection in which diagnosis was difficult, approximately one-half of those tentatively labeled conjunctivitis later proved to be real trachoma.

Is Trachoma Highly Contagious?

Trachoma is not highly contagious: otherwise, it would be more widespread than it is. Because trachoma is more likely to be transferred from one member of a family to another member than to contacts outside the home, it is sometimes referred to as a family disease, but it is not hereditary.

Important factors in the epidemiology of trachoma are general levels of living, particularly as they relate to sanitation and housing conditions, and geography and climate. Migration of infected persons into areas with high standards of domestic hygiene is not attended with danger, but such migration into areas with low standards of hygiene, where geographic and climatic conditions favor the disease, would tend to facilitate its dissemination.

Like other infectious diseases, trachoma is more likely to spread where unsanitary and overcrowded living conditions prevail. Although it is sometimes seen in persons of exemplary habits of personal hygiene, it is more likely to take root in persons who are careless about such matters. The use of a common towel to wipe the face, for example, is an almost certain invitation to the disease. Improvement in economic status, with its concomitant improvement in sanitation and housing, will materially aid in the elimination of the disease.

In general, a high incidence of trachoma is

observed in areas with a high mean temperature and little rainfall and in flood districts near the estuaries of large rivers. In all of these, sun, wind, and dust act as conjunctival irritants and are factors predisposing to the infection. In Missouri, trachoma is prevalent not only in the mountainous areas, where the climate is hot and the air dusty, but also in the cotton-growing lowlands of the southeastern delta, where the climate is humid and windy and the winds are dust laden.

Does Diet Have Any Effect on Trachoma?

According to Rice and his co-workers (25), there is no evidence that a balanced diet supplemented with cod liver oil affected the course of trachoma in 18 untreated patients kept under observation for varying periods of time. However, it is the opinion of this writer, as well as that of other observers, notably Stucky (26) who made a great contribution to the prevention of trachoma in Kentucky, that inadequate diet and avitaminosis are contributory factors. At present, however, this concept must be regarded as unproved.

Glikson (27) states that his observations of over 25 years in Israel indicate that general nutrition is a decisive factor in an individual's immunity to this disease, and he adds that proper diet, including fresh milk and fresh, green vegetables, will shorten the duration of the disease or actually heal it. Murray (28) states that in South Africa adequate feeding supplemented by vitamin concentrates generally brings about a remarkable improvement within a few weeks even if no specific medication other than ablutions with saline is used. According to Bietti (29), if there is any importance in nutritional factors, lack of animal proteins and of calories is more likely to play a role than avitaminosis.

Are All Races Equally Susceptible?

Generally speaking, all races are susceptible to trachoma in only slightly varying degrees. American Negroes seem not to acquire the disease, but miscegenates are not necessarily immune. Murray (28) reports that in South Africa, Negro tribes become afflicted with trachoma to a rather large extent. Extensive sur-

veys indicate that the disease affects about 29 percent of the natives in that area.

In Missouri, the disease predominates among persons of northern European ancestry, notably Irish, Scottish, English, German, and Scandinavian. Their forefathers formed the forward ranks of the pioneers who moved westward from the coastal States, bringing the infection with them. The disease became established in these families and still flourishes in some of their settlement areas, notably in the southern half of the State. Negroes in the State do not acquire the disease.

It is thought by some observers that the dark-pigmented races, especially Negroes, are more immune to trachoma than the light-pigmented ones. Seemingly in support of this contention is the fact that when trachoma in an Egyptian passes over to a European, the disease manifests itself much more rapidly and has a much more devastating effect. Wilson (30) states that trachoma tends toward spontaneous cure more frequently among Egyptians than among Europeans. He observes further that some of the Egyptians suffer little from this disease and that the lesions are mild in comparison with the lesions among Europeans.

Studies by Thygeson (31) indicate that the trachoma bodies show a predilection for the superficial cells of the conjunctiva without involvement of the basal cells and that they tend to spare the pigmented cells. This possibly could explain the resistance in certain dark-pigmented races to trachoma and the more favorable development of the disease among them.

Bietti (32) states that there are racial differences in the sensitivity to the disease and that the Negro particularly is more resistant. He does not maintain that degree of pigmentation is important, but rather that some innate racial characteristic itself is responsible. In support of this theory, he mentions that among various African native tribes of equal pigmentation, some tribes develop the disease more severely and in greater numbers than others.

Rice (33) believes that the severity of trachoma varies considerably in different parts of the world and even within the borders of our own country. He states that trachoma probably does less damage among the Chinese, for

instance, than it does among the white population of Missouri and Arkansas. Factors of immunity and adaptability may even be more important than factors of race.

To sum up, although trachoma is very widespread throughout the Near East and the Orient, the disease appears to be less distressing in natives of these regions than in Europeans and their descendants, among whom the prevalence is relatively low.

Why Does Trachoma Still Exist?

Trachoma still exists because it was so widespread in the ancient civilized world and because, too, it did not receive the advantages of a modern medical campaign until the past 3 or 4 decades. Before the advent of sulfonamides and antibiotics, treatment was largely empirical rather than specific.

Until recently, there was little organized attack against this disease abroad and practically none in this country. The idea of international collaboration in trachoma control has been in existence for almost 100 years, but only with the founding of the Anti-Trachoma League and the International Organization Against Trachoma in 1923 did the idea progress to action. Their quarterly publication, *Revue internationale du trachome*, provides an authoritative and dynamic organ for the consolidation and dissemination of knowledge and facts about the disease.

At present, mass treatment of trachoma has been started by the governments of many foreign countries, notably Formosa, French Morocco, and Tunisia, with the assistance of the World Health Organization, and initial favorable results are reported. Projects are being planned in Yugoslavia and Egypt, and surveys in Western Australia (34) and in South Africa (28) have emphasized the need for action in these areas.

In the United States, a program of attack against the disease was begun in the Appalachian area in 1913 by the Public Health Service (35). During the next 11 years, one or more temporary diagnostic and treatment centers were set up in Kentucky, Virginia, West Virginia, Tennessee, North Dakota, Arkansas, Georgia, and Missouri, and in 1923 a permanent

hospital and clinic center was established at Rolla, Mo., by the Public Health Service in co-operation with the State. In more recent years, the States of the trachoma belt have carried on the battle against the disease.

Can We Rid This Country of Trachoma?

During the past four decades, the prevalence of trachoma has decreased markedly (36). The program against the disease has been changing gradually from treatment of active, florid cases to the practice of preventive medicine and treatment of early and late and terminal cases. As shown by the data in tables 1 and 2, the number of operations performed at the Missouri Trachoma Hospital for trichiasis, entropion, gratage, and lid deformities and the number of cases of trachoma found among field clinic patients are declining steadily.

In the other States of the trachoma belt, the disease is no longer considered a significant problem. Arkansas has discontinued its extensive case-finding program, but within the next few years it will survey former high-incidence areas to see whether the disease has actually been eradicated. In southern Illinois, once an area of high incidence, a marked decline in the number of cases was observed between 1949 and 1953. No active cases have been re-

ported in the State since 1949. Kentucky discontinued its trachoma control program more than 4 years ago, and Oklahoma reports that the disease is now a negligible problem in areas where the incidence was once high. In Arizona and New Mexico, where an estimated 20 percent of the Indian population before 1938 was afflicted with the disease, a 1952 survey of the Indian reservation residents in all areas except Albuquerque found only 2.6 cases per 1,000 population.

With continued organized attack against this disease, it should be entirely wiped out in the

United States in time. Cooperation of independent ophthalmologists in trachoma areas and constant effort to teach the affected people good health habits will aid in reaching this goal. An improved standard of living and a rise in the general socioeconomic status are factors of importance.

What Treatment Is Given for Trachoma?

At the Missouri Trachoma Hospital and generally in this country, the infection is treated with sulfonamide medications. Sulfonamide solutions are used as drops in the eyes several times daily, and sulfonamide tablets administered orally and sulfonamide ointments used nightly are adjunctive therapeutic measures. If the infection is in the early stage, treatment may be completed in approximately 3 weeks; if it is of long duration, treatment may last as long as 2 or 3 months, or even longer if the disease has become established.

Sulfonamides have been used to treat trachoma since about 1938, and most authorities agree they are active against the trachoma virus. More recently, the antibiotics have been used with favorable results in some instances. In the experience of this writer, the sulfonamides have proved more effective than any other therapeutic agents, the antibiotics appearing to be of secondary help (37).

Of the antibiotics, terramycin and possibly aureomycin seem to be most active against the trachoma virus (38-45). Chloramphenicol is considered much less effective, and penicillin, bacitracin, and streptomycin seem to be of little or no value in uncomplicated trachoma.

Mitsui (43, 44) reports that in Japan both acute and chronic trachoma respond well to terramycin treatment; but he observes further (45) that while in his opinion sulfonamides may not be the best agents against trachoma in these days of antibiotics, they certainly constitute a means of treatment in those cases that do not respond to antibiotics alone. Loe, who first used sulfonamides successfully against trachoma in 1937 among the American Indians in the southwest (46), has stated that in his experience the antibiotics have not proved successful in the treatment of this disease in Arizona and New Mexico.

1953-----	395	21	5.3	6	1.5

Cosgrove (47), director of the Arkansas State health program for trachoma control, believes that sulfonamides are the most effective agents against trachoma, and that the antibiotics, including the broad-spectrum group, have no effect against this disease.

Does Trachoma Tend to Recur?

Trachoma is a disease of recurrences and relapses. The infection may have become dormant or latent so that not infrequently an arrested case may later show signs of activity. A recurrence may be due to the patient's having returned to an environment of smoke, dust, or wind, or to a mode of living not conducive to eye health.

Recurrences sometimes result from insufficient or inadequate treatment and occasionally from trauma, scarring, or possibly allergy. Some recurrences, of course, are due to reinfection from a member of the family who has not had treatment. All family members should be examined when trachoma is found to be present in one of them.

Is There a Definite Criterion of Cure?

As yet there is no definite criterion of cure in trachoma. However, a combination of all the negative signs—quiescence of inflammation, deturgescence of the pannus, resolution of the follicles, a smooth, pink conjunctiva with or without cicatrices, absence of inclusion bodies—indicates that the disease is arrested. Without any one of these signs, the patient cannot be considered cured, even if no active lesion is present.

Thygeson (48) points out that, when confronted with the problem of distinguishing healed trachoma from trachoma of low activity, microscopic examination is helpful only in a limited way. The finding of inclusion bodies indicates trachomatous activity, but inability to find them, even on repeated examination, does not necessarily mean a lack of a trachomatous activity.

Is There a Worldwide Clinical Pattern?

Although the cardinal signs of trachoma (follicle formation, pannus, cicatrization, and

the presence of inclusion bodies) are universally accepted, the disease varies considerably in different parts of the world and would therefore seem to be polymorphic. According to Lyons (49), trachoma may show variations in any of the following factors: (a) mode of transmission, (b) average age of onset, (c) clinical course and the resultant disability, (d) conditioning effect of secondary infection, (e) incidence of inclusion bodies at various stages of the disease, and (f) response to treatment with sulfonamides and antibiotics. Reports from workers in different countries illustrate some of these variations.

Lyons (50) states that in Egypt trachoma in its active stages causes surprisingly little disability; that gross thickening of lids is rare and the pannus seldom encroaches on the pupillary zone; and that photophobia and lacrimation are usually minimal and often absent. He adds that it usually is only the corneal lesions caused by neglected trichiasis in the late stage of the disease which lead to any serious reduction in vision.

Mitsui (45) of Japan declares trachoma to be an acute disease in its initial stage without exception. MacCallan (51) states that in Egypt and in eastern Europe, trachoma begins always with an inflammatory stage that continues for some time, but that in England the onset of trachoma in an acute or subacute form rarely occurs. He states further (13) that unmixed trachoma is always a chronic disease: that when it commences with acute manifestations or exhibits acute exacerbations, these are the result of superadded infections. Postic (52) of Yugoslavia observes that Mitsui's statement that all trachoma is acute in the initial stage must be taken to mean that such is the case in Japan, but not necessarily everywhere.

Gradle (6) states that trachoma in the United States varies somewhat with the characteristics of the population and the degree of sanitation present, but that entirely lacking is the onset of acute trachoma associated with ophthalmia, as seen so universally in Egypt. Lavery (53) states that in Ireland the disease usually starts insidiously, and that he has never seen an attack of acute trachoma. He reports, however, that

he has observed attacks of acute conjunctivitis superimposed upon trachoma.

In Missouri, trachoma is usually a chronic disease, progressing slowly over a long period of time; acute trachoma may occur, but only occasionally. In my experience, the disease takes from one to several months to show early clinical signs after contact with a known infection has taken place.

Birch-Hirschfeld (11) believes that the first stage of trachoma with its inflammatory infiltration passes early and imperceptibly into the stage of scarring and that the follicles are not of essential importance for the progress of the disease; that they are found both in early and late trachoma and are usually invaded and broken up by strands of fibroblasts.

The first appearance of the follicles on the conjunctiva may vary as to location. MacCallan (13) notes that in Egyptians the granulations appear first on the tarsus, but in Europeans, in the cul-de-sac (retrotarsal fold of the conjunctiva). Fuchs (12) states that papillary hypertrophy is a predominant feature of the tarsal conjunctiva, and that the retrotarsal fold is the seat of formation for trachoma granules. Among the white population of Missouri, it is in the retrotarsal fold that follicle formation is most pronounced and where the follicles first manifest themselves. When trachoma is seen in the florid form, however, a generalized follicular distribution throughout the conjunctiva of both tarsus and fornix in both the upper and lower lids is found.

In many, but not all, parts of the world, trachoma is frequently complicated with secondary infections, commonly the Koch-Weeks bacillus and the gonococcus (in epidemic and endemic form), and less frequently the Morax-Axenfeld diplobacillus and the pneumococcus. The associated infections greatly affect the clinical picture as well as the prognosis and the infectivity of the disease. Nataf (54) of Tunisia includes trachoma with secondary infections always; he believes that pure trachoma exists very rarely and that numerous infections are very often associated with it, the trachoma itself constituting the basic disease, the endemic and epidemic characteristics of which are conditioned by related disorders.

Do Associated Infections Affect Treatment?

Most authorities agree that the associated infections of trachoma have a conditioning effect on treatment. Lyons (50) states that antibiotics usually produce rapid and striking improvement in secondarily infected cases and have little or no immediate effect in uncomplicated trachoma. Bietti (39) points out that sulfonamide and antibiotic treatments may give different results according to the country in which they are administered. In Egypt, for instance, where associated infections are the rule, the response to treatment by various sulfonamides and antibiotics may well depend on the conditioning effect of these infections, as well as perhaps on other factors. Pages' (55) survey of experiments has shown that the trachoma-bacteria complex is characterized by a kind of mutual stimulation on the part of the associated micro-organisms, or, in other words, a synergic attack. In the United States, where the complicated trachoma common in Egypt is seldom seen, sulfonamides have generally produced more favorable results than the antibiotics (37).

Summary and Conclusions

Trachoma is a disease that may vary considerably in different parts of the world. Its clinical phase may be conditioned by climate, environment, associated infections, race, and general health and living conditions. From a worldwide point of view, therefore, both sulfonamides and antibiotics are useful in therapy, although sulfonamides have been found more effective in the United States.

There is definite need for research on the serology and immunology of this disease and on its causative agent or agents. In this connection, a more simple and more direct diagnostic laboratory test would be of infinite value in making an early diagnosis. A more clearly defined clinical picture of trachoma as it occurs in various regions of the world would make it possible to correlate better the results of chemo-antibiotic treatment. A universally accepted classification of trachoma would help clarify many questions of medical, administrative, investigational, and international character.

Although trachoma has been virtually eliminated from many areas of the world, the job of complete and universal eradication is not yet accomplished. The combined efforts of research, mass therapy, and preventive measures, however, are producing increasingly favorable results. New facts and new ideas in trachematology are being brought to light and are being set forth in the literature. These reports help to define the disease, to recognize its variations, to make possible early diagnosis, and to determine the therapeutic methods most suitable for coping with it regionally.

The outlook today for a worldwide attack on trachoma is more encouraging than ever before, particularly because of better understanding between ophthalmologists and trachomatologists here and abroad; and because, too, of greater recognition by governmental authorities of the importance of this disease in relation to the health, economy, and welfare of the affected people.

STOP RHEUMATIC FEVER

Health Education Unit

A film, a discussion guide, and a general information booklet and folder make up the new health education unit recently released as part of the "Stop Rheumatic Fever" campaign being conducted by the National Heart Institute of the Public Health Service and the American Heart Association.

The unit provides materials for use in State and community programs for the prevention of rheumatic fever—a leading cause of disability and death in childhood and producer of heart damage in children, adolescents, and young adults. The materials are based on medical recommendations for preventing rheumatic fever. These recommendations were drawn up by the American Heart Association's Council on Rheumatic Fever and Congenital Heart Disease and were published in the April issue of *Public Health Reports*, p. 373.

Done entirely in animation with much human interest appeal, the film symbolizes rheumatic fever as a smoky flame which sometimes flares up, sometimes lies almost dormant—the character of the disease itself. Streptococcus infections that come from the germs which cause sore throats, tonsillitis, scarlet fever, and some other diseases are symbolized as the forerunner of rheumatic fever.

The guide provides a synopsis of the film. It suggests pertinent remarks for the user to make before showing the film, including a sample 2-minute introduction. Delineated are important points to be emphasized in discussion after the film is shown. Information useful in answering audience questions and sources for further information are given.

The booklet offers a condensed version of the film content and is illustrated with pictures from the film. It provides information about streptococcal infections and on what to do about them to prevent rheumatic fever. It is useful for distribution to film audiences to aid in retention of content and for future reference and also as educational literature in general health information and rheumatic fever programs.

The folder describes rheumatic fever and its association with a preceding streptococcal infection. It helps parents to know when to call a physician and what to tell him about their child's sore throat. It contains a chart of questions on signs and symptoms, helpful in determining whether or not a child has a "strep" sore throat. Affirmative answers indicate the need to call a physician promptly.

FILM. Stop Rheumatic Fever. 16 mm., sound, black and white, 12½ minutes, 1955. Prepared by National Heart Institute, PHS. Produced by Transfilm, Inc. Cleared for television.

Audience: General public. Suitable for showing before parent-teacher groups, in the classroom, community health meetings, luncheon clubs, and other similar meetings. On television may be used as complete presentation, or preliminary to a physician's talk or other discussion.

Available: Purchase—American Heart Association Film Library, 13 East 37th Street, New York 16, N. Y. Price \$15. Rental distribution not being made since purchase price is so low.

DISCUSSION GUIDE. 4 pages. Copy accompanies each print of the film. Single free copies obtainable from American Heart Association, 44 East 23d Street, New York 10, N. Y., or from local heart associations.

BOOKLET. Stop Rheumatic Fever. Public Health Service Publication No. 420. 1955. 16 pages. Single free copy accompanies film. Additional copies obtainable from the National Heart Institute, Bethesda 14, Md. Quantities may be purchased from Superintendent of Documents, Washington 25, D. C., at \$4.00 per 100.

FOLDER. Now You Can Protect Your Child Against Rheumatic Fever. Free copy accompanies film. Additional copies available from the American Heart Association, 44 East 23d Street, New York 10, N. Y., or local heart associations. Quantities are \$1.65 per 100.

An octopus-like representation of the streptococcus germ, closely resembling its microscopic appearance.

A Rural Sanitation Program

—Lancaster County, Nebraska—

By LESTER A. SANGER, C.E.

THE DEVELOPMENT of rural sanitation programs has followed at quite a distance the development of sanitation programs in urban and fringe areas of relatively high population density. This is an understandable pattern assuming that the magnitude and importance of environmental sanitation problems are directly proportionate to the population density. However, the isolation of rural villages and farm homes is rapidly fading, and the rural population now contributes measurably to the environmental health problems of a region.

There are many ways to develop a rural sanitation program, and it would be improper to draw any inference that the procedures in Lancaster County, Nebr., are necessarily a model for others to follow. The procedures may, however, contribute to the planning of programs in similar areas.

The prelude to the sanitation program in Lancaster County was the reorganization of the health department.

Community Profile

Lancaster County covers 864 square miles of gently rolling farm land and has 21 small

towns, 6 of which range in size from 200 to 450 people. Exclusive of the city of Lincoln, with a population of approximately 100,000, the county has a population of about 20,000. The people are of German, Bohemian, Dutch, Russian, Irish, and English descent. There are 80 rural schools and 15 consolidated town schools.

During 1945 and 1946 the Lincoln City Health Department was reorganized to meet the standards of a modern full-time local health unit. This involved the addition of professional public health personnel to the staff and major revisions in the organization and activities of the department.

The civic groups that were instrumental in the modernization of the Lincoln City Health Department, chiefly women's organizations, joined hands with their rural counterparts and began to "beat the drums" for the organization of a combined city-county health unit. They recognized the desirability of extending health services to the fringe areas surrounding Lincoln and, indeed, to the entire county.

Meetings with numerous civic groups and rural organizations were followed by public hearings conducted by the board of county commissioners during the winter of 1946-47. These public meetings were interesting demonstrations of democracy in action. It was conspicuous that the decisive force for the organization of the combined city-county unit came from several women leaders in the community and the organizations they represented. The

Mr. Sanger is the director of the division of sanitation, Lincoln-Lancaster County Health Department, Lincoln, Nebr.

Lincoln-Lancaster County Health Department became a reality July 1, 1947.

The Rural Sanitation Program

A preliminary survey of the county revealed that the geographic distribution of environmental sanitation problems could be classified into four main groups:

1. Fringe areas adjacent to Lincoln.
2. Town areas (including the usual problems of food sanitation, private sewage disposal, water supplies, insect and rodent control).
3. Farmstead sanitation (water and sewage).
4. Schools (rural and town).

The Lincoln-Lancaster health department chose to launch the rural sanitation program through the medium of a school sanitation program. It would permit the department to distribute a service uniformly throughout the county. Many sanitary improvements in the school environment were needed, and the county superintendent of schools was not only the respected authority throughout the rural school system, but also he was influential within the family of county officials.

During that first school year, the rural sanitarian made a complete survey of all rural and town schools. The survey consisted of checking on the standard items of school sanitation: water supply, toilet facilities, school lighting, and so forth.

In most schools the survey was conducted as an educational experience for the teacher and children, especially in the one-room rural schools. At every opportunity the sanitarian stressed the importance of a safe school water supply and sewage disposal system, and emphasized that the same applied to their own farm wells and toilet facilities.

Long before the survey of all schools was completed, the health department began receiving requests to talk at Grange and parent-teacher association meetings. These meetings provided the opportunity to introduce the parents to public health in general, to the services we could give for the asking, and, in particular, to specific details of safe farm water supplies and sewage disposal systems. The

meetings followed a somewhat standard form—formal presentation of the material supplemented with a short movie on some aspect of public health and followed by the customary informal discussion.

These informal gatherings and the free discussions that followed were of great value in helping the sanitarian to get personally acquainted with many people and facilitated release of the typical reserve of rural mid-westerners.

Requests for participation in these rural meetings soon overburdened the rural sanitarian, and it became necessary to obtain assistance from other members of the staff, notably the public health educator and public health nurses. Many requests for speaking engagements and technical services were received through the county extension agent. The county agent contributed as much as, or more than, any other individual to the introduction of health services among the rural populace. He contributed further to the program by donating the first set of septic tank forms.

By November 1947 we were getting calls from all over the county for technical assistance in planning the layout of septic tank systems and for advice on how to improve private water supplies.

Septic Tank Installations

The demand for septic tank installations made it necessary to build two more sets of forms. We built one set and induced a local lumber company to build a set. For each use of the forms, we charged a rental fee of \$5.00 to cover maintenance and replacement of forms.

Each request for assistance was handled approximately as follows:

1. A date was set for the sanitarian to visit the home, lay out the system, and explain to the farmer what materials he needed to make the installation.

2. On the day the ready-mixed concrete was to be delivered for the tank and distribution box, the sanitarian was there several hours ahead of delivery time to make a final check on the setting of the forms, construction aids, and other details. The sanitarian on these occasions was not dressed to attend a wedding. I mention dress-

Figure 1. Septic tank work sheet.

Definition of Points

- A. Point at foundation where house plumbing must leave the building in order to provide slope of $\frac{1}{4}$ " per foot in sewer line to septic tank. (May vary 2" up or down.)
- B. Reference point marked on side of building.
- D. Grade stake at ground surface at site of septic tank.
- E. Center of sewer line entering septic tank.
- F. Point at bottom of septic tank excavation.
- G. Point at top edge of septic tank wall.

NOTE TO PLUMBER:

The house sewer pipe must leave the building at point A (2" + or -) which is _____ ft., _____ in. below point B marked on outside of house. The center of discharge end of sewer to septic tank (E) must be _____ ft., _____ in. below grade stake D (2" + or -).

NOTE TO SEPTIC TANK CONTRACTOR:

The tank is to be located _____ ft. from dwelling.
 The hole for septic tank must be dug to a depth (D-F) of _____ ft., _____ in.
 The top edge of form (G) must be _____ ft., _____ in. below grade stake D.

Sanitarian _____

ing appropriately as much because of the unheralded public relations significance as provision against construction errors. The sanitarian usually remained at the site until the concrete was in place.

In planning the installation, the sanitarian chose the location for the septic tank, distribution box, and disposal field. By use of an inexpensive surveyor's level (\$54) he established a profile for the entire system. After establishing the profile, he filled out in duplicate a septic tank work sheet (fig. 1). One copy was given to the farmer and the other was placed in the office files for possible future reference.

Many modifications of the features shown in figure 1 were used, but, generally, they have been installed with a house sewer slope of $\frac{1}{4}$ inch per foot, free discharge into the tank, no baffles, 3-inch drop in flow-line between tank inlet and outlet, T-connection on effluent line, 500-gallon concrete tank with sectional cover slabs, observation ports in septic tank cover and distribution box cover, depth of liquid in septic tank of 4 feet, distribution box provided with baffle and several standby discharge openings (plugged), and 3 to 6 separate tile lines for disposal field.

One noteworthy modification of the tile field used occasionally is an installation we have called an "under-drain system." It consists of two levels of drain tile separated by 24 inches of gravel, the lower-level tile discharging into a stream or ravine ultimately seeking disposal by way of natural surface drainage. The idea is not new, but our experience indicates that this is a very satisfactory method in cases where, due to soil density, ground water, or space limitations, conditions do not favor the standard tile system.

The health department has installed approximately 200 concrete septic tanks with its forms and has supervised at least another 100 systems using poured-in-place concrete, precast concrete, tile, or metal septic tanks. Many of the systems have been revisited to see how well they work and to check on certain technical details.

During a check of several systems in January 1950 (2 years following installation), tanks that had little or no protective earth covering were particularly noted. Although the winter temperature had averaged 18° F. for more than a

month, the temperature of sewage in tanks with concrete cover slabs exposed, averaged 41° F. A distribution box with only a loose piece of canvas as a temporary cover showed a liquid temperature of 38° F.

Another significant observation was the relatively larger volume of scum than is indicated in the literature on septic tank operation. In most installations the depth of scum was equal to sludge depth, and in some the scum depth exceeded sludge depth. Probably, the primary contributing factor is the higher percentage of animal fats and greases that the farm home discharges in its sewage, and to this extent, at least, domestic farmstead sewage is different from urban sewage.

In all of the installations, the influent sewer pipe terminates approximately 1 inch beyond the inside face of the septic tank wall and discharges the incoming sewage by free fall. In spite of the extensive buildup of scum, in no case was any obstruction to the incoming sewage observed.

From these observations, the sanitarian has concluded that the following principles of septic tank construction in this area are sound.

1. With a minimum of earth covering, there is no reason to fear freezing in septic tanks, distribution boxes, or tile fields.

2. More consideration should be given to sludge storage capacity in tanks serving rural homes; any baffling that would restrict sludge storage capacity is considered detrimental.

3. Free-falling influents are totally satisfactory operationally, simple to construct, less expensive, and facilitate maintenance of the house sewer.

Peeking into the digestion chamber and bowels of an operating septic tank system may lack esthetic appeal even for conscientious sanitarians, but these explorations were of great value in reinforcing junior sanitarians' confidence in the accepted principles of septic tank sewage disposal systems.

Private Water Supplies

Requests for help in improving private water supplies throughout the county paralleled requests for aid in installing septic tanks. In private water supply improvements, above-

ground installations using some of the established principles of good well construction were stressed, and many improvisations were used.

Although Lancaster County does not have all types of surface geological formations influencing problems in well construction, there are enough of them to tax the sanitarian's inventiveness. One of the most unique problems is the scattering of underlying salt beds. To avoid these salt water horizons, we often called on the State geologist to help locate new wells. The source of ground water in Lancaster County is, for the most part, obtained from the mantle-rock of unconsolidated glacial drift. The salt water horizons giving trouble in relatively shallow private wells generally occur along the valleys of Salt Creek and its main tributaries. Salt Creek, running diagonally across Lancaster County from southwest to northeast, is the major stream in the county. Also, in some areas of the county there are pockets of impervious shales and clays, yielding their entrapped water with extreme reluctance.

Due to these geological restrictions and the cost of drilling new wells, the greatest challenge was to rehabilitate existing wells. Except in wells requiring only the elimination of well pits, most of the rehabilitation work dealt with tile-cased and dug wells. With few exceptions these wells were altered by replacing the existing upper 10 feet of tile casing or well wall with 4- or 6-inch diameter steel well casing.

The program of improving farm water supplies was on a voluntary or promotional basis. Consequently, there were no inhibiting restrictive regulations in making these improvements. In private wells, there is at least as much individuality as with human fingerprints, and the great variety of unorthodox but extremely practical techniques a resourceful sanitarian can use in improving farm water supplies is remarkable. The sanitarian has used so many old cultivator wheels, windmill sway-bracing, hog fencing, and the like, in rural sanitation work that he has difficulty interpreting the neat drawings normally attached to approved standards and regulations.

Another complicating factor in the private well improvement program was the occasional occurrence of excessive nitrate nitrogen

($\text{NO}_3\text{-N}_2$) in wells. Several cases of infant cyanosis (methemoglobinemia) were reported, and investigation revealed that high nitrate nitrogen in private well water supplies was the causative agent. A complete analysis of this problem would constitute a separate report, but the following comments are considered sufficient as a summary here.

In a group of 30 wells showing nitrate nitrogen concentrations in excess of 10 p.p.m., ranging from 10 to 108 p.p.m., construction alterations to prevent entrance of surface contamination into the wells have effectively reduced the objectionable nitrate nitrogen. Although numerous articles on the subject suggest that nitrate nitrogen is, in some cases, indigenous to a particular aquifer, our experience in Lancaster County strongly indicates that high nitrate nitrogen in well water is due to either a direct short circuiting of surface contamination into the well, or a recent indirect zonal contamination of the aquifer. Partial chemical analyses on investigated private water supplies have become somewhat routine along with the sampling for bacteriological analyses. This activity of the program is considered a good example of teamwork between the public health nurse, the health officer, and the sanitarian.

Local well drillers are, of course, an indispensable part of the well improvement program. Well drilling is characteristically an inherited craftsmanship, and unfortunately some of the old well drilling practices are not in harmony with present day standards of sanitation. It requires more than a little tact and perseverance to convert the well driller to these new ideas; to question his methods is tantamount to insulting his grandfather. In spite of these inherent characteristics, it is essential to indoctrinate the local well drillers with good sanitary practices. If this is properly accomplished, sanitarians will soon discover many new wells of good construction on which they were not even consulted.

Town Water Supplies

When the rural sanitation program was started, only one of the four town water supply systems was an approved above-ground instal-

lation. All pits have now been eliminated and in other respects altered to comply with State health department regulations.

These improvements were accomplished by a combination of techniques—repeated visits with town officials, attendance at council meetings, insistence on frequent sampling and analyses of their supplies. Also, we were opportunists. In one town, complaints of tastes and odors from residents necessitated major repairs to an oil-lubricated vertical turbine pump, and the town officials were convinced that other improvements might just as well be made at the same time. In another town, a spring flood gave us an assist. While muddy flood waters were still knee deep in the town pump house, the sanitarian invited the town water commissioner to wade out with us to see how things looked. It wasn't good. A series of samples showing evidence of contamination helped us on the third well.

In addition to improving existing town wells, three other towns have been induced to construct water supply systems. As in the case of town well improvements, these new water supply systems were the culmination of executive and public meetings with town boards reinforced with survey data on contaminated private wells and the mingling of private sewage disposal systems with private wells. These three new town systems are of the same basic design: 6-inch steel cased well, vertical turbine pump, pressure tank—all housed above ground in a neatly constructed pump house (fig. 2). They have a cast iron distribution system with fire hydrants. The average population of these towns is 170 people.

Rural Food Establishments

At the time of meeting with town boards to discuss water supplies, the sanitarian also requested permission to inspect local taverns and cafes. It was considered essential to contact town officials before entering the eating and drinking establishments. With the exception of taverns, our program of food establishment sanitation has not been on an enforcement basis. By resolution of the city-county board of health, the same general sanitation regulations of the Lincoln food ordinance, patterned after the

Figure 2. New town well prior to construction of pump house.

Public Health Service Ordinance and Code, are to apply to food and drink establishments elsewhere in the county. On rare occasions, the health department has appealed to the town boards to help in getting corrective action.

Taverns are issued licenses by the State liquor commission through the county commissioners of the respective counties. We have a working agreement with our county commissioners whereby no license is approved until they have received a satisfactory sanitation report from our department. This has been very successful in gaining improved sanitation in these places, and there are seldom any difficulties with the operators.

Other Activities

There is opportunity to supply numerous other services in a rural sanitation program, some by request and others by promotion. As the services of the department became known throughout the county, we received many calls in the nature of nuisance complaints. Several spring floods afforded us the opportunity to give emergency service during the floods, and following floods we conducted spraying operations in towns as fly and mosquito control measures. We always made a special effort to be conspicuously present (sincerely) in all areas affected by the floods, even at the expense of being up at all hours of the night. Any town isolated by flood waters was contacted by phone to show our concern for the town well or private water supplies. The county commissioners purchased

a power sprayer for our use in spraying operations in the county. We have conducted town surveys on private sewage disposal facilities and in this way have induced incorporated towns to adopt more comprehensive sanitary codes.

In retrospect it seems that there are almost limitless opportunities to give worthwhile services in a rural sanitation program.

Summary

It is proper and requisite that local health services be expanded to include rural sanitation activities whenever local interest is favorable. Based on experiences in Lancaster County, Nebraska, the following generalized comments are submitted as possible guides in the development of rural sanitation programs in other areas.

1. Before launching a rural sanitation program, a careful study should be made of the sanitation problems, local prejudices, personalities, and attitudes. Keep in mind that it may not always be advisable to assault the problems of highest public health priority.

2. A rural school sanitation program is a convenient and effective way of introducing the rural sanitation program to the rural community. It results in a prompt demonstration of services, uniformly distributed over the area,

and has a better than even chance of a warm reception.

3. Regular and periodic visits with key officials (county commissioners, superintendent of schools, town boards, county extension agent) is an essential rule of conduct.

4. Re-indoctrination of local well drillers is essential to the extension of properly protected private water supplies.

5. Installing properly constructed septic tank sewage disposal systems is the most demanding of all activities of the sanitarian's time and energy. Procedures for properly installing these systems should be streamlined as rapidly as possible; local contractors should be informed of the essential specifications and induced to do the work without direct supervision by the sanitarian.

6. To be successful, the rural sanitarian must like evening meetings with rural people. He must be friendly, sincere, and patient.

I am convinced that skillful application of the principles outlined are as essential to a successful rural sanitation program as technical knowledge of the sanitary sciences. Conducting a rural sanitation program is a rewarding and satisfying experience; it has no equal as a training ground for sanitarians, and no other activity in sanitation affords such an opportunity for the exercise of diversified talents.

PHS Exhibits

Diagnostic Techniques

Three exhibits—"Breath Sounds on Tape," "Heart Sounds on Tape," and "Screening for Diabetes"—specially designed for teaching devices and refresher courses may be borrowed from the Public Health Service.

Breath Sounds on Tape

Tape recordings of normal and abnormal chest sounds prepared by Dr. William B. Walsh of the Georgetown University Medical Center are synchronized with illuminated chest films in a 4½-minute cycle. The continuous tape may be heard through a bank of stethoscopic earphones or from a loud speaker.

Breath sounds on tape was exhibited at the 1954 scientific show of the American Medical Association in San Francisco.

The exhibit weighs 1,300 pounds and requires a booth 14 by 20 feet.

Heart Sounds on Tape

Recordings of heart sounds, prepared under the general direction of

Dr. W. Proctor Harvey of the Georgetown Medical Center, have been used by the Public Health Service as an exhibit.

The exhibit with high-fidelity sound equipment offers a 5-minute sample of heart sounds with explanatory comment. These sounds may be heard with head phones or a loud speaker.

A full set of teaching tapes, which require about 4½ hours for the com-

plete run, may be borrowed, together with the special playback equipment.

The exhibit weighs 1,400 pounds and requires a booth 14 by 20 feet.

Screening for Diabetes

An exhibit featuring a continuous three-dimension motion picture, in color and with narration, has been produced by the Public Health Service to demonstrate the Wilkerson-Heftmann method of blood screening for diabetes.

This true glucose screening test can be performed in the physician's office in about 5 minutes at a cost of about 15 cents.

Although the exhibit (including the film) will not be distributed generally, it is available for showing at national and State medical meetings.

A booth 10 feet deep and 20 feet wide is required for the showing. The exhibit weighs 681 pounds.

For information about these exhibits, write to the Division of Special Health Services, Public Health Service, Department of Health, Education, and Welfare, Washington 25, D. C.

Public Health Speaks

"Public Health, an institution of the people and for the people, needs to speak out, unafraid," states the program for the 43d annual session of the North Carolina Public Health Association which was held in Raleigh, September 23-25, 1954. Three of the several papers dedicated to this theme are presented here in brief form. A fourth, *Where Do We Go From Here in Public Health?* by Dr. Wilson T. Sowder, will be published in full in an early issue of the American Journal of Public Health.

Efficient Management In Health Departments

Continued progress in public health depends in part on research and increased knowledge in the health sciences, but of equal or even greater importance is the efficient application of the knowledge to meet the needs of the public.

Overall Administration

In this day when there is a tendency to look intently at overhead expenses of all agencies, some State boards of health seem inclined to dispense with State and district supervisory personnel and assign them as field workers. Some departments are discussing the idea of replacing registered nurses with licensed practical nurses, sanitarians with "inspectors," and

health officers with lay administrators. Is this because of a real shortage of personnel and the fact that individual staff members are better trained and therefore need less supervision and management? Or is it because our management is so indifferent and inefficient that those in control of the money feel that it can be more effectively used by employing a larger staff of lesser trained and qualified personnel at lower salaries?

If the health officer is concerned only with the medical aspects of his job and pays little attention to efficient management of his staff and program, then the question may well arise, could not his full time be spent as a clinician and he be replaced with a qualified lay administrator? In small- and medium-sized health units of 6 to 8 employees, we should strive to have every member of the staff so well educated and trained as to require a minimum of supervision. In units with large staffs, it may be possible to save money by the use of lesser trained and qualified personnel, such as practical nurses, nurse aides, and inspectors, to carry on routine functions in clinics or to check on nuisance complaints. But when such personnel are to be used, it becomes mandatory to

By C. L. Guyton, M.D., M.P.H., assistant State health officer of South Carolina.

have well-trained and well-qualified supervisory staffs.

Recording and Using Health Data

Basic responsibilities of a health department are the recording and analysis of data on births, deaths, and notifiable diseases; maintenance of registers of individuals known to have certain diseases or disabilities; and the collection and interpretation of morbidity data from all available sources. Analysis of these records will frequently bring to light unrecognized health needs.

There is need not only for a record system that contains health data but for one that records activities of the staff and contains all the data that can and will be evaluated to the betterment of the service. Records should list such things as home visits, clinic attendance, and facilities inspected or surveyed. More important, they should tell what has been accomplished as a result of these activities. Such records will assist staff members in planning their day-to-day work, serve as a basis for program evaluation and revision, and become documentary evidence of work accomplished. But, before instituting a new record, always ask yourself, will it be useful and will it be used? A record that will serve only to collect data and dust should not be adopted.

Registers of persons known to have certain chronic diseases or impairments are usually kept and referred to with a great deal of pride by the administrator. Frequently, however, they are not put to good use because they are not analyzed and reviewed from time to time. A study of these registers will often show that certain diseases tend to be more prevalent in certain geographic areas or among certain social and economic groups. This should lead to an evaluation of that particular program to determine if it is meeting the needs of this particular area or group.

Health Education and Information

Every public health worker is engaged daily in health education. Every public health activity is, or at least should be, of health educa-

tion value. Otherwise, the activity has been inefficiently performed.

However, we must also have a planned program of health education and information; otherwise, the community will soon take our activities for granted. Like any other program, this one must always have a definite objective. If we decide to stimulate or motivate the public through newspaper articles or radio or television programs, then these must be for a definite purpose. If a film is to be shown, it must be directed toward a definite educational goal. Classes should be well planned, and the teaching should be supported by all the educational media available.

Group teaching can save much time in giving basic information on diet, preparation of formulas for babies, operation of food-handling equipment, and the like. However, we should not forget the adage: "What I hear I forget. What I see I remember. What I do I know." This means that classes and group instruction will have to be supplemented with individual counseling and teaching regarding those activities that the individual must "know."

Fortunate is the health unit that has a trained health educator on its staff, for he is an expert in the efficient management of all the tools of health education. Every State department of health now has one or more health education consultants. They can be of great assistance not only in health education programs but in stimulating community interest in health activities and in planning the overall program of the local unit.

Supervision and Regulation

The laws of our States give health departments legal authority to supervise and regulate many activities in the field of health. If a department frequently finds it necessary to resort to legal action, then it is performing this responsibility in an inefficient manner. Health laws and regulations are usually established to set a standard and to serve as a starting point for the education of those concerned. Legal action to enforce them should be the last resort.

Is it not better to keep in touch with housing projects and to contact the development agency

early so as to inspect the site, test the soil, and agree on size of septic tanks, for example, than to wait until the buildings and tanks are completed and we are asked to make final inspection? We should prevent public health problems as well as disease.

Are we to continue our programs of inspecting dairies, food-handling establishments, and other institutions in a routine manner with a check sheet and grade card? When are we going to organize classes for operators and their staffs to educate them to operate their facilities properly and to assume responsibility for compliance with regulations? When are we going to include counseling as an integral part of inspection programs?

Direct Environmental Health Services

With the rapid advancement in health consciousness by the public and the rise in our economic level and general standards of living, many of the direct environmental health services are no longer required. They could be dispensed with if we educate the public regarding them sufficiently for individuals and families to assume more responsibility for the control of their environment. The efficient health department will engage only in those activities which require the use of trained public health personnel and which cannot be carried out by lay persons and groups.

Now that we have practically eradicated malaria, are we to continue a spray and fogging program to keep people comfortable? Or are we to educate the public that this activity is no longer a health measure and should be transferred to another agency?

Are we to keep on advocating the building of pit privies in rural areas when we know full well that even a trained health educator could not motivate you and me to use one in the cold gray dawn of a winter's day? Would it not be better to raise our vision from the lowly pit and observe the new power lines that have been extended into rural areas and to persuade the home owner to install an electric water pump, which eventually will lead to the installation of a plumbing system and proper sanitation of the entire home environment?

Personal Health Services

Improved sanitation and the use of modern drugs and treatment have markedly reduced the need for some of our immunization programs. If administration of personal health services is to be efficient, we must review our morbidity data and adjust our immunization programs to fit present-day community needs.

Are we to continue routinely to give typhoid inoculations to large groups of citizens now living in a sanitary environment, without a single case of typhoid over a period of years, just because we have trained them to submit to the annual roundup? Would it not be better if we analyzed the morbidity records and surveyed the environmental sanitation of the various communities and then limited such programs to areas where they are needed?

When are we going to stop limiting our rabies control program to the immunization of household pets and the vaccination of children and begin to attack the problem at its main source by preventing stray dogs from running at large in the community?

Are we going to continue to conduct chest X-ray surveys in which we routinely X-ray the same persons year after year, even though we find little or no tuberculosis among them? Would it not be better to concentrate on those communities and those social or economic groups which are less readily available but which would yield much higher dividends in cases diagnosed?

Are we going to continue inspecting school children by the thousands just because we have them congregated in an easily accessible place and wish to point with pride to a large number of individual services? When are we going to concentrate our activities on those pupils that have been screened out by teachers and nurses?

Operation of Health Facilities

We constantly preach efficiency in the operation of restaurants and schools and in the sanitation of homes and their environment, but, I ask in all sincerity, are we efficient in our health centers, auxiliary centers, and other places where clinics are conducted? Just because we use an auxiliary center a few hours once or

or terminal malignant disease. A few of these patients have had remissions. Some remissions were brief, but others continue. Another new antibiotic has been shown to exhibit carcinostatic activity. The growth of mammary adenocarcinomas in mice has been inhibited.

Experimental studies on fungal infections, previously refractory to all antibiotics, indicate that a number of new antibiotics possess sufficient antifungal activity to warrant clinical trial. One group of these was obtained from among the products of streptomycete filtrates. Another new antibiotic has been tried in experimental mycotic infections in mice with considerable therapeutic success. Approximately 75 percent of the test animals survived cryptococcosis, coccidioidomycosis, and sporotrichosis. A number of other agents have exhibited an ap-

preciable fungistatic effect in preliminary laboratory studies.

The reports revealed a continuing search for new antibiotics. Organizations which have already discovered or developed a number of useful agents appear to be intensifying their efforts for still more advanced preparations with respect to breadth of spectrum, greater tolerance, and greater pathogenic specificity. The 14 new antibiotics reported at the symposium are given in the table.

Safety Measures

Measures stressed during the symposium to enhance the safety of antibiotics and prevent abuse in using the agents were:

1. Elimination of the indiscriminate or incorrect use of antibiotics.

2. Systematic and comprehensive education in antibiotic application at the undergraduate, graduate, and postgraduate levels.

3. Wide public dissemination of the fact that self-medication is dangerous and that the common practice of demanding antibiotic medication from physicians should be abandoned.

4. Proper labeling of all antibiotics with warning as to the possible toxic reactions and the dangers of indiscriminate use.

The symposium was sponsored by the Department of Health, Education, and Welfare, Food and Drug Administration, Division of Antibiotics, in collaboration with the journal *Antibiotics and Chemotherapy*. The proceedings have been published under the title of "Antibiotics Annual, 1954-1955," and may be purchased from Medical Encyclopedia, Inc., 30 East 60th Street, New York 22, N. Y.

Program for Juvenile Delinquency

Ten long-range goals designed to improve methods of dealing with juvenile delinquency have been outlined by the Division of Juvenile Delinquency Service in the Children's Bureau.

The new division is seeking to help States and communities:

1. Acquire, in every community of 20,000 or more population, at least one police officer with special training in working with juveniles. Bigger cities will need a specialized juvenile division.

2. Make good detention facilities and services available to every juvenile court in the country so that juvenile delinquents will not have to be detained with adult criminals.

3. Provide expert physical and psychological examinations for each youngster in serious trouble before the courts decide what kind of care and treatment is needed.

4. Staff all courts with civil service probation workers trained in social services for children.

5. Establish juvenile court laws and practices that meet the standards recommended jointly by the National Probation and Parole

Association, the National Council of Juvenile Court Judges, and the Children's Bureau.

6. Provide for juvenile delinquents training schools that have complete programs of education, health, mental health, recreation, and followup and provide one staff member for every 15 youngsters.

7. Focus the training on the individual youngster to help him find a satisfying, responsible role in the community.

8. Establish in each State at least one special institution for emotionally disturbed youngsters, separate and apart from adults.

9. Provide coordinating mechanisms through which public welfare, health, mental health, employment, courts, policy, training schools, and educational agencies can plan programs and pool experiences with private agencies.

10. Make regular and comprehensive reports on what is happening to juvenile delinquents so that States and communities and the Nation can measure progress toward the goal of an irreducible number of youngsters who get into trouble with the law.

Adequate prenatal care is also essential. It must include a complete history and physical examination followed by periodic examinations at stated intervals. The initial examination is not complete unless it includes a serologic test for syphilis and a determination of the Rh status. A chest X-ray is certainly highly desirable and perhaps should be mandatory. The mother must be encouraged to report any irregularities, and any untoward signs or symptoms must be explored immediately.

Nutrition Important

Recent research studies of nutrition and pregnancy point up the fact that nutrition means more than counting calories. These studies indicate that when the prospective mother's diet is good and deficiencies are corrected by supplements, the incidence of toxemia is lower than when nutrition is inadequate. They show that fetal and neonatal mortality rates and the incidence of premature birth are lower among mothers whose diet is adequate. They further point out that toxemias of pregnancy are more prevalent in women who are underweight than in those whose weight remains within average limits. To preserve the health of mothers and infants, a sound nutrition program must be promoted.

The prospective mother must be protected against syphilis and tuberculosis. A diagnosis of syphilis demands all our efforts to cure or arrest the disease; these efforts will, in turn, almost always protect the fetus. A diagnosis of tuberculosis demands close medical observation, supervision, and education throughout pregnancy and the removal of the infant from the maternal environment immediately after birth.

In view of what is known of the role of German measles during early pregnancy and its effect on the child, measures for the prevention of this disease must be instituted.

The Basic Program

The prime objective in maternal hygiene is the conservation of life and health of the expectant mother and her developing infant. This objective leads us to promote a program in

which medical care is made available to every pregnant woman and in which she is persuaded to obtain care throughout the maternal cycle.

It is desirable that this service be provided by a single physician of the patient's choosing, but when unavailable in this way, the service should be provided through community facilities.

The seriousness of activating a program of maternal survival is accentuated by this fact: In any year of recent date, there were more deaths as a result of complications and sequelae of pregnancy than there were deaths from such communicable diseases as diphtheria, scarlet fever, poliomyelitis, meningitis, and typhoid fever. When one realizes that deaths related to pregnancy occur in only one period of life and in only one sex, the gravity of the situation is readily apparent.

Preventing Infant Deaths

The salvage of lives of infants and children within the last 25 years has been the major factor in the increase of life expectancy. Progress has been made in reducing mortality not only in the infant age group (0-1 year) but also in the later periods of childhood. Had mortality rates of a half century ago prevailed last year, approximately 1,000,000 children aged 15 years and under would not be with us today. However, little if any progress has been made in preventing death during the first 28 days of life. The shorter the period of time after birth, the less marked has been the rate of decline in the death rate.

The causes of death in the newborn period are rather poorly defined, more so than in later infancy. Prematurity, congenital malformations, birth injuries, infection—these are the most frequently cited causes.

In a broad sense, we recognize certain hazards as contributing to infant mortality and particularly to neonatal wastage. Specifically, we recognize hazards of development and hazards of injury. We know that defects in development occur and that these may culminate in a monstrosity or congenital malformation. We also know that toxemia or an infection such as syphilis or influenza in the mother may exert its effect on the fetus. Mechanical injury to the

mother, injury to the infant incident to difficult labor, abortion—all these contribute to many preventable infant deaths. Exhaustion of the infant in trying to overcome an impassable barrier, injury to the cranial vault through injudicious use of forceps, and toxemic conditions in the mother further add to infant deaths, many of which perhaps are needless.

How shall they survive? Since factors contributing to early infant death, even fetal death, have their incipient stages in prenatal life, early and continuous medical supervision of the mother is as necessary for preventing infant deaths as for preventing maternal deaths. Constant medical observation of the mother permits detection of deviations or complications early enough for remediable measures to be instituted.

Medical supervision of the infant must begin immediately after birth. If conditions are favorable, the infant should receive a complete physical examination. Persistent medical and

nursing observation should follow. In home deliveries it is imperative that the public health nurse be involved to the extent of postpartum visits. The nurse, however, is cautioned to refer her observations first to the family physician.

Although premature birth is recognized as a sign rather than a diagnosis, it is recorded as the greatest killer of infants. The premature infant is born saddled with the threat of death. But many premature infants can be saved. Properly equipped and staffed hospitals which provide proper management of a premature delivery will go a long way toward this end.

If none of the three major killers of the newborn—prematurity, congenital malformation, or birth injury—is involved, the next compelling duty is the prevention of infection. It is here that the public health nurse plays a major role. Through her efforts, the mother is stimulated to maintain early care and observation of her child.

Missed Opportunities In Tarheel Sanitation

PHR In this era of expansiveness—bigger production, greater markets, tremendous planes, stupendous bombs—public health is not unaffected, and there are those in our ranks who cast ever about for this and that new world to conquer. Nor is such wholly to be abhorred; rather it is commendable, provided merely that the conquering is in order.

But it does pay, at times, to take stock; to see where we stand; to search out the failures and the missed opportunities in order to achieve

improvement. Missed opportunities could be found in nursing or health officering or health educating—in any of the numerous public health persuasions. But it is sanitation shortcomings that will get the extra special treatment today. And have we here the makings of an epic, a saga of woe, a list of “it might have beens” the like of which Maud Muller never even dreamed?

Milk and Meat

At the front of the parade of bedraggled specters is the Tarhell milk supply, fittingly white and at times elusive, as becomes a proper ghost. But we can't even call this a near miss: we're wide of the mark a country mile. It is devoutly to be desired that someday milk sanitation will be placed with the State board of health where it belongs. But, lest my remarks be interpreted as the anti-agrarian rantings of a noncomprehending city clicker, let me add that I would urge the use of the “Federal Order” in those areas of the State where producer protection is required.

By Millard B. Bethel, M.D., M.P.H., health officer for the city of Charlotte and Mecklenburg County, N. C.

So it is with milk, and so it need not have been. Had we been more astute, the whole business could have been tucked neatly away by now.

And so it will be with meat one day unless we all face up to the situation. There has been an awful lot of awful meat foisted upon North Carolina consumers. We in public health are in large measure squarely to be blamed, and, sooner or later, we shall pay the penalty. It is not enough for us to have reasonably good, reasonably clean abattoirs—or even perfect ones, for that matter. Meat, and poultry, too, must have ante-mortem and post-mortem inspection. Yet, few communities are doing even a fair job; and none of us can claim credit for a good job when poultry is considered.

Unfortunately, shade-tree meat is even more common in North Carolina than is barnyard milk. Our job will not be done until we have made them both a rarity.

The people in my town and my county are neither better nor worse than in yours. What we see in the Queen City is fairly representative of what is going on elsewhere in the State. Adulterated and contaminated foods need ever to be guarded against. Some will always be avaricious enough to add water to milk, and where there's little chance of being caught chicanery will be rampant. And as long as Old Bossy is held more dear than the Old Gray Mare, some unethical entrepreneur will put horsemeat into hamburger. You might say these practices are largely fraudulent and hence not within the realm of sanitation. I contend they are both and that good local sanitarians backed by good local or regional laboratories can make it all a bitter memory for the errant, a triumph for decency, and another safeguard with which we ought to surround our people.

Stream Pollution

We are coming to grips in some measure with stream pollution and with refuse and garbage disposal but our local authority ought to be greater. Our urban laws are strict compared to those that prevail just beyond the corporate limits. Yet, some of the circumferential territory is much more thickly populated than certain areas in the town—and it is the same in half a hundred Tarheel communities—but we are not cloaked with sufficient legal authority to do a needed job there. I daresay, however, that even without extended authority we can find a few unturned stones. Let's get active in this business of stream pollution and waste and garbage disposal.

We have a hybrid job in the field of local public health—that of air pollution, occupational hazards, and accidents. In State health departments and in very large local health departments, there are appropriate bureaus, sections, or units at work in these fields, but such is out of the question in small local units. One can't call accidents, air pollution, and occupational hazards exactly missed opportunities in sanitation, but on the local scene they come close. We must try to match this hybrid job with a "hybrid" man. A crack sanitarian with special knowledge in these fields would be sure to earn the meager pay we'd be sure to grant him.

And thereby hangs the end of my woeful tale. For all those jobs, for this endless array of work, let's keep struggling to get good men—train them, pay them, and work their fingers to the bone. Get that kind of men, give them enlightened supervision, and back them with a good laboratory, and we shall have many fewer missed opportunities.

Patients in Mental Institutions, 1950 and 1951

Public Health Service Publication No. 356. 1954. 429 pages. Price \$2.00.

This report was compiled from the 25th and 26th annual censuses of patients in mental institutions, the fourth and fifth such censuses to be conducted by the National Institute of Mental Health. It contains data on hospitalized patients with mental diseases and on patients in institutions for mental defectives and epileptics, both public and private.

More complete and greatly expanded over similar previous studies, the report contains 178 statistical tables showing certain characteristics of first admissions, resident patients, discharges, personnel, and expenditures. A bookkeeping account of the flow of patients into and out of mental hospitals and institutions is also given.

Immunization Information For International Travel

Public Health Service Publication No. 384. 1954. 56 pages. 20 cents.

Official information on the immunizations required by each country as well as the immunizations recommended by the Public Health Service as precautionary measures for persons traveling abroad is contained in this pocket-sized book.

Other items include an explanation of the procedure for having vaccinations recorded on the International Certificates of Vaccination form; a list of designated yellow fever vaccination centers; and maps showing the areas of the world in which yellow fever is endemic and the yellow fever receptive areas of the United States.

Travelers may obtain information

on subsequent changes in immunization requirements from the Public Health Service or from State and local health departments and shipping and airline offices.

The Physician in the U. S. Public Health Service

Public Health Service Publication No. 394. Revised 1954. 14 pages. 15 cents.

One of a series of pamphlets devoted to careers in the Public Health Service, this booklet describes opportunities for physicians in clinical medicine, research, epidemiology, administration, quarantine, and foreign service.

Basic information covers requirements for admission to the commissioned corps, duty assignments, rotation, pay scales, and benefits. Detailed information is given about activities in the various Public Health Service hospitals and the research program at the National Institutes of Health. The role of the Public Health Service in cooperating with local health organizations in carrying out public health programs is discussed and examples are given of emergency epidemiological services provided by the Service. Opportunities in overseas health missions are also covered.

Sources of Morbidity Data, Listing Number 2. 1954.

Public Health Service Publication No. 399. 90 pages.

The second listing of projects in the files of the Clearinghouse on Current Morbidity Statistics Projects contains descriptions of 126 projects meeting the clearinghouse criteria, and supplements the 206 projects described in Listing Number

1 (Public Health Service Pub. No. 332).

As in the first listing, the projects are grouped into sections by major type of disease, injury, or impairment, with the following information, if available: (a) abstract of the project, (b) the organizations participating, (c) names and addresses of the principal investigators, (d) publication plans and references, and (e) the name of a person to contact for further information.

The statistical results of studies are purposely omitted because the clearinghouse is not intended to provide the findings from morbidity studies but rather to show where such data may be found.

Listing Number 2 has a section of supplementary notes on projects in Listing Number 1, which consists of information obtained through unsolicited comments from principal investigators whose projects were listed, or information collected by the clearinghouse staff in the course of other work.

The listings of the clearinghouse are published primarily for the use of actual and potential contributors and for other research workers in the fields of public health and medicine. Persons requesting information from the clearinghouse services are urged to specify the type of study in which they are interested.

This section carries announcements of all new Public Health Service publications and of selected new publications on health topics prepared by other Federal Government agencies.

Publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications issued by other agencies.

Data on patients admitted to the National Leprosarium at Carville, La., show that leprosy in the United States is concentrated in a few areas of a few States. Nevertheless, the disease may appear in any section of the country.

Leprosy in the United States

By L. F. BADGER, M.D.

THE EARLIEST available reference to leprosy in the United States is found in Romans' Concise Natural History of East and West Florida, which reports the occurrence of the disease in that area as early as 1758(1). By 1766, the disease was sufficiently prevalent to cause the Spanish commissioner of Louisiana to establish a leprosarium near the mouth of the Mississippi River. From this evidence, it may be assumed that leprosy has existed in this country for at least 200 years.

The disease has been reintroduced frequently since its first appearance; primarily from Europe and Africa during the early years; later, from Asia; and, since the acquisition of extra-territorial possessions, from the Caribbean and Pacific islands.

The prevalence of leprosy in the United States, past or present, is difficult to determine. Many cases have not been recognized, and some cases known to physicians have not been reported. No nationwide case-finding program

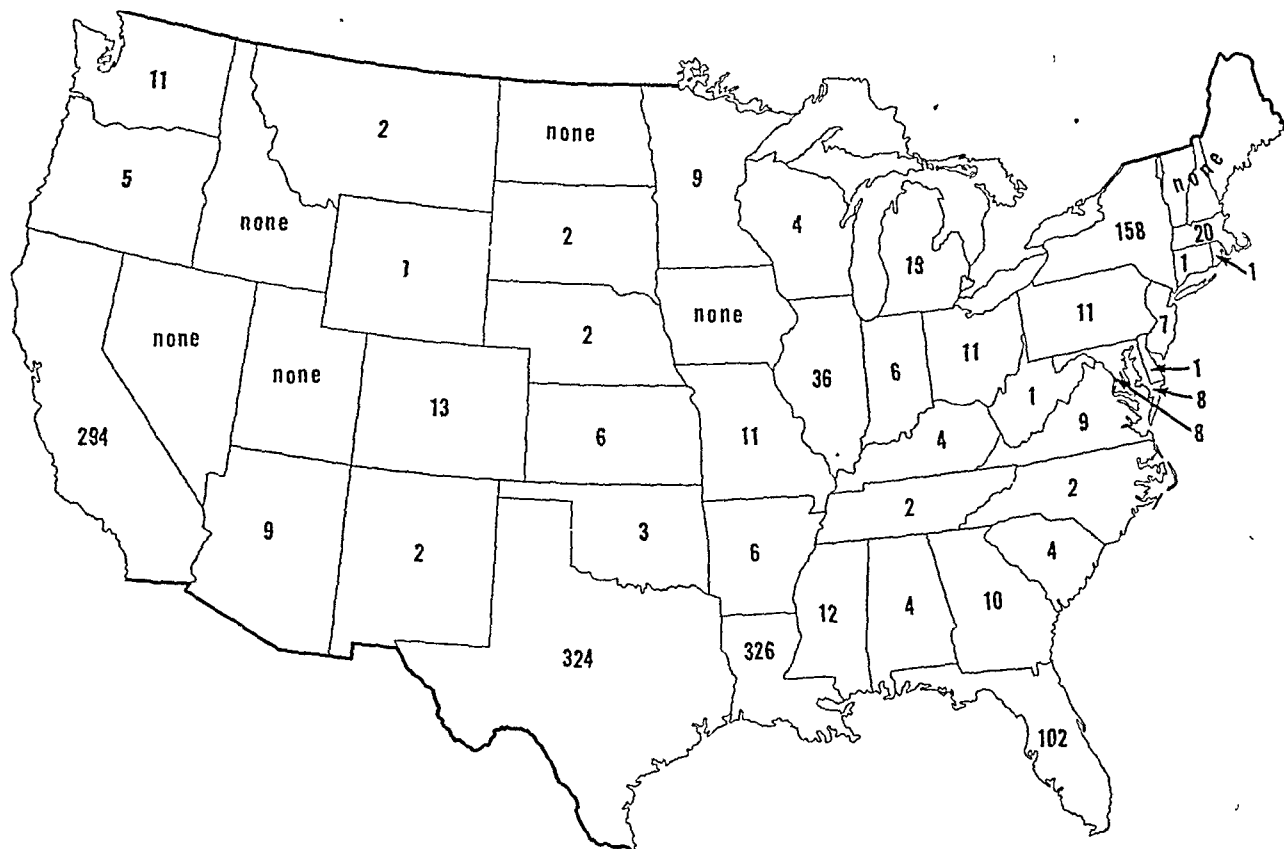

has ever been conducted. However, an idea of the number of cases in recent years can be obtained from the records of the National Leprosarium at Carville, La. From the opening of that institution in early 1921 through 1953, 1,465 individual patients were admitted. One or more patients were admitted from 40 States and the District of Columbia (fig. 1). Thus, the disease may appear in any section of the country. (The State from which admitted was not recorded for four patients.)

Of the 1,465 patients, 637 (43.5 percent) were foreign born and 822 (56.1 percent) were American born. The birthplace of six patients is not known. Generally, throughout the 33-year period, the number of American-born patients exceeded the number of foreign-born patients (fig. 2). (As used in this report, foreign born applies to patients born outside continental United States, and American born, to patients born within continental United States.)

Most of the patients, 1,204 (82.4 percent), were admitted from the States of New York, Florida, Louisiana, Texas, and California. From Florida, Louisiana, Texas, and California, States in which the disease has been considered endemic, 1,046 (71.6 percent) were admitted. (Although leprosy is no longer held to be endemic in California, for the purpose of this review California is classed as it was in the past.) The majority of the California pa-

Dr. Badger since 1949 has been chief of the Leprosy Control Unit, Communicable Disease Center, Public Health Service, Atlanta, Ga. In most of his assignments during his 24-year career with the Service he has been concerned with leprosy investigation and control work.

Figure 1. States from which patients were admitted to the National Leprosarium, 1921-53.

tients (80.6 percent) and of the New York patients (89.2 percent) were of foreign birth. The majority of the Florida patients (86.2 percent), of the Louisiana patients (95.4 percent), and of the Texas patients (74.8 percent) were born in the United States (table 1).

From 1940 through 1953, 476 patients were admitted to the leprosarium, as compared to 486 for 1931-40 and 503 for 1921-30. These figures suggest a slight downward trend. The decrease may be attributed in part, however, to the fact that in recent years patients with tuberculoid leprosy have not always been admitted to the leprosarium. The decrease is accounted for largely by a decrease in the number of foreign-born patients.

In addition to the patients admitted to the National Leprosarium, information has been obtained on 355 leprosy patients in the four endemic States who were not admitted. The number of patients in other States who were not admitted is at present unknown. Thus, a total of 1,820 patients were either admitted to the leprosarium or were known to have the dis-

ease during the period 1921-53. It is impossible, however, to state with any degree of accuracy the total number of cases that actually occurred during that period.

Foreign-Born Patients

The 637 foreign-born leprosy patients admitted to the National Leprosarium give an idea of the extent to which leprosy has been imported into the United States in recent years. The majority of these patients probably became infected before they entered this country, and some of them were sources of infection in American-born patients. However, there is reason to believe that some of the foreign-born patients contracted the disease from infected associates after their arrival in the United States, as will be shown later in this paper.

Foreign-born patients have been admitted to the leprosarium from all sections of the country (table 1), and they have come from more than 50 different political entities (table 2). The majority of the foreign-born patients who

Figure 2. Percentages of National Leprosarium patients of foreign birth and of United States birth, 1921-53.

appeared in the Atlantic Coast States were born in European countries or the West Indies; of those who appeared in the Gulf Coast States, in the West Indies or Mexico; and of those in the

Pacific Coast States, in Mexico, the Pacific Islands, or Asia.

During the 33-year period, the number of patients of foreign birth declined more than the total number of patients fell. The yearly average number of foreign-born patients dropped from 25.0 during the period 1921-35 to 14.5 during the period 1936-53. There were 30.6 percent fewer foreign-born patients admitted during the second period than during the first. The greatest decrease, 67.7 percent, occurred among European-born patients. Patients native of Asia decreased 34.3 percent, and those native of the West Indies decreased 36.5 percent. Patients born in Puerto Rico, however, increased 100 percent, and those born in Mexico increased 22 percent.

A number of foreign-born persons in whom clinical leprosy developed after their arrival in the United States were not admitted to the leprosarium. In California, for example, 248 cases of leprosy were recognized among persons born in Mexico, but only 100 were admitted.

¹ Includes Territories and possessions of the United States. ² Birthplace of 3 not recorded. ³ Birthplace of 1 not recorded. ⁴ Birthplace of 2 not recorded. ⁵ State from which admitted not recorded.

The majority of the remaining 148 apparently returned to Mexico either voluntarily or through deportation procedures.

American-Born Patients

American-born patients were admitted from 33 States and the District of Columbia (table 1). Ten or more patients were admitted from only 7 States: the 4 endemic States and Illinois, Mississippi, and New York.

Not all of the American-born patients contracted the disease in this country, nor did all of them become infected in the States from which they were admitted. Many became infected while residing in endemic countries, and others, while residing in endemic States.

The number of American-born patients admitted to the leprosarium has been rather constant. The yearly average for 5-year periods from 1921-50 ranged from 22.4 to 31.0, and the yearly average for 1951-53 was 18.0.

Concentration in States

Leprosy among persons born in the United States is concentrated in Florida, Louisiana, Texas, and, to a lesser extent, California. Of the 820 American-born patients, 740 (90.2 per cent) were either admitted from or born in these four States. A majority of the foreign-born patients were also admitted from these States, most of these, however, from California.

Florida

A total of 137 cases of leprosy were recognized among Florida residents during the period 1921-53. Admitted to the leprosarium were 102 of the patients.

Of the 137 patients, 111 were born in the continental United States and 96 were born in Florida. Thus, leprosy in Florida seems primarily to concern Florida-born persons.

Of the 22 patients of foreign birth, 16 were natives of the West Indies—11 of the Bahama Islands and 5 of Cuba. Of the 15 patients born in other States, 1 was a native of Louisiana, and 14 were natives of nonendemic States. (The birthplaces of 4 patients were not recorded.)

1921-30.....	33	3.3
1931-40.....	31	3.1
1940-50.....	28	2.8
1951-53.....	4	1.3

Louisiana

Leprosy was first recorded in Louisiana in 1766-68, when cases occurring among the French were isolated at Balize at the mouth of the Mississippi River (2). In 1785, a hospital was established in New Orleans for the treatment of persons afflicted with the disease, and in 1894, the Louisiana Home for Lepers was established near the village of Carville. In 1921, this institution was acquired by the Federal Government and became the National Leprosarium.

Both the West Indies and Canada have been considered as sources of leprosy in Louisiana. According to Dyer (3), "The popular impression . . . that leprosy in Louisiana came with the Acadians from Nova Scotia . . . was due, no doubt, to the fact that among the descendants of these people leprosy has existed, but the evidence seems to point to the fact that the disease came rather through the West Indies, particularly Martinique . . . and Cuba."

From 1921 through 1953, 350 cases of leprosy were recognized in the State, and 326 of the patients were admitted to the National Leprosarium.

As in Florida, leprosy in Louisiana is primarily a problem in persons born within the State: 313 of the 350 patients were born in Louisiana. Of the 18 patients born in other States, 6 were natives of Texas, 1 was born in California, and the remainder were natives of nonendemic States. Of the 15 foreign-born patients, 1 was born in Canada, 3 in Mexico, 1 in South America, and the remainder in Europe. (The birthplaces of 4 patients were not recorded.)

The trend in Louisiana-born patients also appears to be downward, as shown by the data below. There were 45.6 percent fewer cases

recognized during the period 1941-50 than during the period 1921-30.

	Number	Yearly average
1921-30.....	125	12.5
1931-40.....	109	10.9
1941-50.....	68	6.8
1951-53.....	11	3.6

Texas

In Texas, 393 cases of leprosy were recognized during the 33-year period. Of these patients, 324 were admitted to the National Leprosarium.

Information concerning the origins of the 69 patients not admitted to the leprosarium is unavailable. Of the 324 admitted, 241 were born within the continental United States, and of these, 202 were born in Texas and 17 in the adjoining endemic State of Louisiana. Of the 81 foreign-born patients, 77 were natives of Mexico. Thus, leprosy here concerns primarily natives of Texas, Mexico, and Louisiana.

The fact that rather large numbers of Texas patients were born in Mexico or Louisiana indicates that the disease in these areas is related. Further evidence is found in these facts: Of the 202 Texas-born patients, 39 had Mexican-born parents; 32 had one parent of Mexican birth; and 5 had one parent born in Louisiana.

The majority of the 39 Texas patients born in other States probably became infected after they entered Texas. Of 20 patients born in nonendemic States, 11 had lived only in these States prior to entering Texas. They entered Texas at ages ranging from 6 to 44 years, and experienced onset of the disease in from 7 to 51 years. Seven of the 20 had lived also in other endemic areas. Of the 17 Louisiana-born patients, 11 had lived only in that State but had had no known contact with the disease. When they moved, their ages ranged from early infancy to 69 years, and the onset of the disease occurred in from 2 to 56 years. One Louisiana-born patient experienced onset of the disease before he left that State; another had had contact with an infected relative; and three had lived also in endemic countries. Of 2 California-born patients, one experienced onset of the disease before leaving that State. (Histories for 4 of the 39 patients were incomplete.)

The number of Texas-born patients admitted

to the National Leprosarium has been rather constant.

	Number	Yearly average
1921-25-----	8	1.6
1926-30-----	20	4.0
1931-35-----	44	8.8
1936-40-----	33	6.6
1941-45-----	34	6.8
1946-50-----	44	8.8
1951-53-----	19	6.3

California

Cases of leprosy recognized in California numbered 521. A few more than half of the patients, 294, were admitted to the National Leprosarium. Of the 103 admissions during the period 1921-30, 31 occurred in 1922. Prior to 1921, California had its own leprosarium, and undoubtedly many of the patients admitted in 1922 had previously been hospitalized in that institution.

Leprosy in California is primarily a disease of the foreign-born. Of the 521 patients, 436 were of foreign birth, 41 were born in other States, and only 34 were born in California. (The birthplaces of 10 patients are not known.)

Foreign-born patients. The birthplaces of the foreign-born patients reflect the immigration pattern of the State: 394 of the patients were born in the Orient, the islands of the Pacific, or Mexico. The greatest number, 248, were natives of Mexico.

Although most of the foreign-born patients probably became infected before they entered this country, it seems likely that a number of them contracted the disease after entry through contact with infected associates. This opinion is supported by the following data for Mexican-born and Philippine-born patients on elapsed time between entry into the State and onset of the disease (patients who had experienced onset of the disease prior to leaving Mexico not included):

Elapsed time (years)	Mexicans: 91 (percent)	Filipinos: 40 (percent)
Less than 10-----	30.7	82.5
Less than 15-----	57.1	87.5
More than 15-----	42.8	12.5
More than 20-----	29.6	2.5

If it should be assumed that each of these patients became infected before entering the

United States, it must be assumed also that the incubation period, for some reason, was of much longer duration among the Mexicans than among the Filipinos. There are, however, two other possible explanations for the difference:

1. Many of the Mexicans may have become infected during visits to Mexico subsequent to their initial entry into the United States. Histories of such visits have been obtained for some of the patients. The Filipinos, on the other hand, are less likely to have made frequent visits to the islands of their birth.

2. Some of the Mexican-born patients may have become infected in California, where there was ample opportunity for contact with infectious cases.

The difference in the length of time between entry and onset is not because the Filipinos were younger than the Mexicans when they migrated to the State. In fact, the Filipinos were slightly older than the Mexicans, as shown by the following tabulation:

Age (years)	Mexicans (percent)	Filipinos (percent)
Under 10-----	10.9	2.2
Under 15-----	23.0	11.1
Under 20-----	46.1	37.7
Over 20-----	53.8	62.2

The possibility that some of the Mexican-born patients in California contracted the disease after entry is further supported by the fact that the elapsed time between entry and onset for Mexicans admitted from California was considerably longer than the elapsed time for Mexicans admitted from nonendemic States, as shown below:

Elapsed time (years)	California: 91 (percent)	Nonendemic States: 37 (percent)
Less than 10-----	30.7	64.8
Less than 15-----	57.1	81.0
More than 10-----	42.8	35.1
More than 15-----	29.6	18.9

American-born patients. The majority of the American-born patients in California probably became infected elsewhere, but a few may have contracted the disease in the State.

Of 34 patients born in California, 16 gave no history of having lived outside the State and may be assumed to have become infected in the State. Six of these 16 had had contact with cases in the family.

Figure 3. Concentration of leprosy in Key West, Fla., 1921-53.

Of the 30 patients born in nonendemic States, 10 had not lived in an endemic State or country before entering California. One of these 10 had lived in Wisconsin, Oregon, and Washington. Six had lived only in Arizona, but onset of the disease occurred in 1 before he left that State, and in 2 others 4 to 6 years after they left. One had lived only in Ohio and Illinois, and one had lived only in Minnesota. The tenth had been a merchant seaman, visiting many ports in endemic countries, and experienced onset of the disease 6 years after he settled in California.

At least 6 of the 11 patients born in endemic States other than California probably became infected before they entered the State.

Concentration in Limited Areas

Not only is leprosy confined largely to a few States in this country, it is also confined to a limited area in each of these States.

In Florida, cases were recognized among residents of only 11 of the 67 counties during the 33-year period, and among residents of only 8 counties during the last 10 years of that period.

The disease has been concentrated in one county, Monroe, and within this county, in Key

West. Of the 137 cases in the State, 44.5 percent were recognized in Monroe County. Of the 96 Florida-born patients, 44.5 percent resided in Key West at the time of diagnosis. Moreover, case histories for 94 Florida-born patients indicate that 78 of these patients probably contracted the disease in Key West.

Within Key West, the disease has been concentrated in a restricted section of the city. Of the 65 patients residing in the city while the disease was active, 56 lived within the outlined area on the map in figure 3, and 39 lived within the shaded area, an area about 5 blocks square. (The address of one patient was not determined.)

In Louisiana, the disease has been concentrated in the lower half of the State. Of the total of 350 patients, 95.1 percent resided in this section: 71.7 percent, in the 9 parishes in the southeastern part of the State; and 46 percent, in Orleans Parish. Cases have been recognized in 27 of the 35 parishes in the southern half of the State, but in only 4 of the 29 in the northern half.

The disease in Texas has been concentrated in the southeastern part of the State. Patients were admitted to the National Leprosarium

from only 53 of the 254 counties. More than 10 patients were admitted from only 7 counties; the patients from these 7 counties represented 68.2 percent of the total from the State. Only 1 patient was admitted from each of 23 other counties.

The 521 patients in California resided in 33 of the 58 counties when they were admitted to the leprosarium or when the disease was recognized. Ten or more patients resided in 11 of the counties, and 293 patients lived in San Francisco or Los Angeles County. There has not been as definite a concentration of cases in limited areas in California as in the other endemic States, but, as noted previously, many of the California patients apparently were infected outside the State.

This concentration of leprosy in limited areas is important because in many instances it is related to the possible source of infection. Particularly is this true in the consideration of the source of infection in members of the armed forces. There is a tendency to consider the source of infection of a serviceman who was born in or had lived in one of the endemic States as that State regardless of whether or not he later spent time in another endemic State or in an endemic country. Actually, if he had lived only in the northwestern part of Texas, for example, his opportunity for becoming infected was no greater than if he had lived in Colorado or Oklahoma.

Dispersion From Endemic States

Leprosy in the endemic States is also important as it relates to the disease in the non-endemic States. Forty-six patients born in the endemic States were admitted from 19 nonendemic States and the District of Columbia (fig. 4). Eight were born in Florida; 14 in Louisiana; 15 in Texas; and 9 in California.

The majority of these 46 patients probably became infected before they left their State of birth, and in some instances they have been sources of infection in persons living in non-endemic States. In 16 of the patients, the disease had become clinically manifest before they left their State of birth. Another 4 patients entered the armed services directly from the State of birth, and in each of these the onset

occurred within 2 years after they entered the service.

Eleven patients had lived only in nonendemic States after they left their State of birth and before the disease became manifest. In 4 of these the onset of the disease occurred within 4 years after they left their State of birth; in 8, within 15 years; and in 3, after more than 15 years.

From the histories of 7 of the 46 patients, it seems likely that they became infected while in foreign countries: Three had served as members of the armed forces in the Philippine Islands; two had lived in China; one in Japan; and one in Hawaii. The histories of the remaining 8 patients are insufficient for analysis.

Nonendemic States

During the period 1921-53, 415 patients were admitted to the National Leprosarium from 36 nonendemic States and the District of Columbia. Of these, 288 were born outside continental United States and 126 were natives of the United States. (The birthplace of one is not known.)

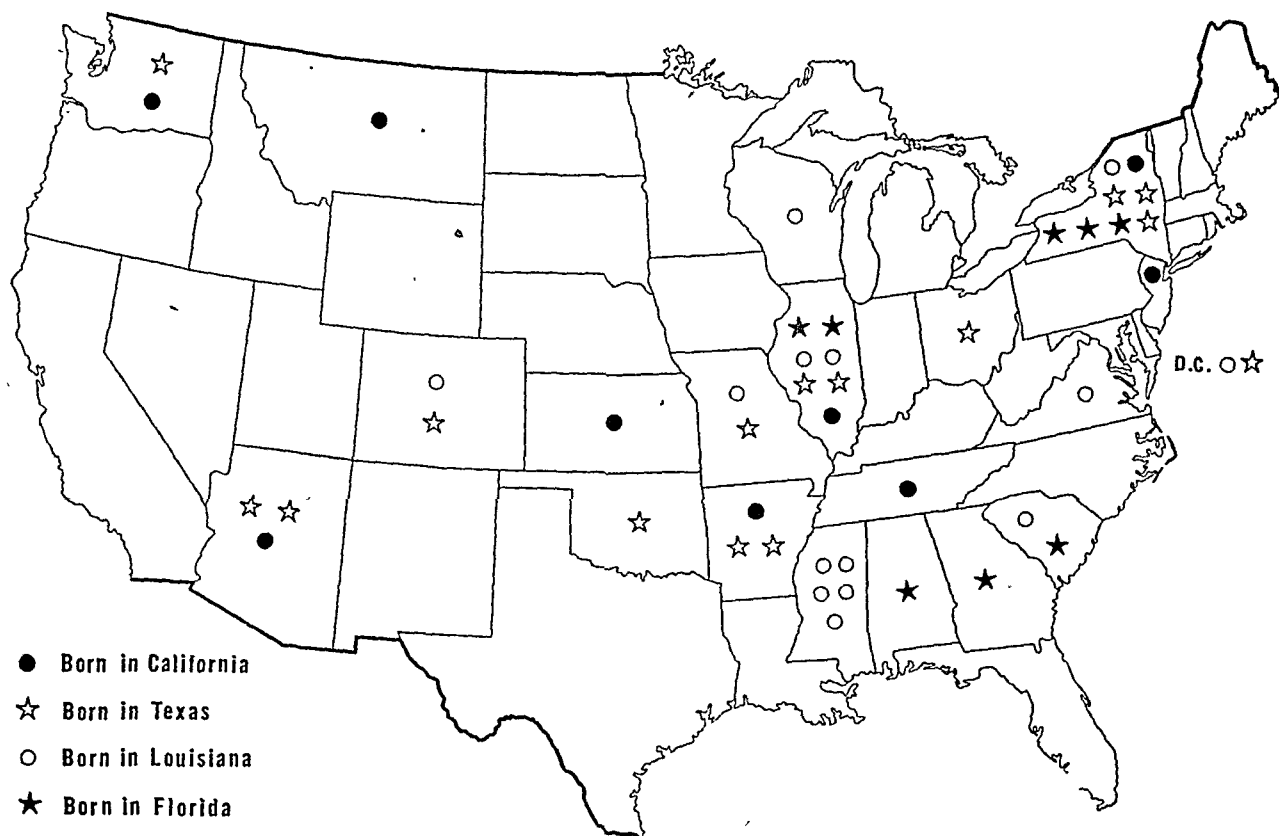

Of the foreign-born patients, 140 were admitted from New York State and 148 were admitted from 28 other nonendemic States and the District of Columbia. The greatest number of the foreign-born patients were natives of Mexico, and the next greatest number were natives of the West Indies.

The 126 American-born patients, who were admitted from 29 nonendemic States and the District of Columbia, may be categorized as follows:

Born in endemic States.....	46
Born in nonendemic States, resided in endemic areas prior to onset of disease.....	20
Born in nonendemic States, visited or traveled in endemic areas prior to onset of disease.....	6
Born in nonendemic States, served as members of armed forces in endemic areas prior to onset of disease.....	18
Born in nonendemic States, resided only in non-endemic States.....	33
Incomplete history.....	3

The majority of these patients had opportunities for becoming infected while in an endemic State or foreign country. The 46 pa-

Figure 4. Nonendemic States from which patients born in endemic States were admitted to the National Leprosarium, 1921-53.

tients born in endemic States have already been discussed. In several of the 20 who lived in endemic areas sometime after birth, the onset of the disease occurred before they left the area, and in others, shortly afterward. The 18 patients who had served in endemic areas as members of the armed forces experienced onset of the disease in from 1 to 13 years after such duty: In 9, the onset occurred within 5 years; in 15, within 10 years; and in 17, within 15 years (date of onset not given for 1 patient).

If the histories of the 33 patients who specified that they had never lived or visited in an endemic area are correct, it must be assumed that they became infected while living in nonendemic States. Nine of them gave definite histories of contact with known cases of leprosy in the nonendemic State. The possibility exists, of course, that some of the patients had visited in endemic areas but failed to give such information to the interviewers.

A majority of families in the United States in which the disease is recognized are single-

case families, and the sources of infection are apparently extrafamilial infectious cases. With such low prevalence of the disease in the nonendemic States, it is not surprising that so few cases have occurred. Undoubtedly, if there were areas in these States in which the disease was concentrated as it is in the endemic States, more cases would occur.

Of the patients who had never lived in an endemic State, the number who had lived only in northern States is about the same as the number who at some time had lived in the southern States. This strongly indicates that, providing there is ample opportunity for contact with the disease, it would occur in any part of the country, north or south.

New York State

The leprosy situation in New York is unique in that, although the disease is not endemic, a large number of patients have been admitted from the State.

The reporting of leprosy is not required in New York State, although it is in New York City. Persons with the disease are not always admitted to the National Leprosarium. Occasionally, persons residing in endemic States move to New York when they learn that they have the disease, and a few patients have absconded from the leprosarium to that State. Information on many of these persons, however, is insufficient for analysis; the following discussion therefore relates only to patients originally admitted to the leprosarium from New York.

Of the 158 patients admitted from New York, 140 were of foreign birth and only 18 were born within continental United States. Of the latter, only 2 were born in New York.

From the available information concerning the American-born patients, the majority probably became infected before entering the State. One patient, however, almost certainly became infected in the State. He had lived in New York City until the age of 42 years (1923), when he visited in Italy for 3 months. On his return the disease was recognized, and he was sent to the leprosarium from the Immigration Station. The onset of the disease had occurred in 1921. Another patient may have become infected in New York. Born in Tampa, this patient moved to New York at the age of 6 years. There he lived with his aunt, who had moved to New York from Florida a year after she developed clinical manifestations of leprosy. The aunt was admitted to the leprosarium 6 years after moving to New York, and 9 years later onset of the disease occurred in the nephew.

Of the foreign-born patients, the greatest number, 59, were natives of the islands of the West Indies, and the next greatest number, 34, were natives of the countries of Europe. As in California, it seems likely that some of the foreign-born patients in New York contracted the disease after entry into this country. With 158 patients admitted to the leprosarium and many more not admitted, there has been ample opportunity for contact with infectious cases within the State. Nearly one-half (47.4) of the patients admitted were admitted more than 5 years after the onset of the disease; 17.5 percent, more than 10 years after onset. As shown

in the following tabulation, the length of time between entry into this country and onset of the disease was considerably longer for European-born patients than for patients born in the West Indies:

<i>Elapsed time (years)</i>	<i>Europeans: 24 (percent)</i>	<i>West Indians: 35 (percent)</i>
Less than 10.....	33.3	82.8
Less than 15.....	66.6	94.2
More than 15.....	33.3	5.7
More than 20.....	25.0	2.8
More than 30.....	8.3	0

Based only on the number of admissions to the leprosarium, the trend of the disease in New York is downward. There were 51 percent fewer patients admitted during the period 1936-53 than during the period 1921-35. Patients of European birth decreased 82.7 percent, and those of West Indian birth, 15.6 percent. Although the number of patients from Puerto Rico is small, patients native of this island increased 70 percent. Whether the apparent downward trend is actual or due to a decrease in the admission of recognized patients is not known.

Summary

Leprosy in the United States is a definite, though not a great, public health problem. The disease may occur in, and be transmitted in, any section of the country. Although a large proportion of the recognized cases have occurred in persons of foreign birth, a majority have occurred in natives of the United States. It must not be assumed, however, that all the patients of foreign birth became infected before entry into the United States, although a majority probably did. In the majority of American-born patients, the disease was contracted in this country.

A majority of the cases have occurred among residents of New York, Florida, Louisiana, Texas, and California, and most of the American-born patients have been natives of Florida, Louisiana, or Texas. The disease has been concentrated in restricted areas of Florida, Louisiana, Texas, and California. A number of patients recognized in the nonendemic States became infected in the endemic States.

International Conference on Arid Lands

The need for a unified research approach to problems of water supply and food production in areas where water is scarce was stressed at the International Symposium and Conference on the Future of Our Arid Lands.

The meetings, held at Albuquerque and Socorro, N. Mex., from April 26 to May 4, 1955, were sponsored by the American Association for the Advancement of Science and its Southwestern and Rocky Mountain Division and were supported by the National Science Foundation, the Rockefeller Foundation, and the United Nations Educational, Scientific, and Cultural Organization.

Col. Omar Draz of the Egyptian Army Veterinary Corps, director, desert range development project, Desert Institute, Heliopolis, Egypt, in his address on the adaptation of plants and animals to arid conditions said, "The growing world population, together with the need to raise the standard of living for millions of people who suffer hunger or malnutrition, makes the increase of the world food production an urgent and vital requirement."

The symposium consisted of four technical sessions on: variability and predictability of water supply in arid regions; improved use of present resources; prospects for additional water sources, including questions on the practicability of weather control, demineralizing saline water, and re-using waste waters; and adaptation of plants and animals to arid conditions.

The American Association for the Advancement of Science will publish the symposium papers and specific recommendations of the conference. Further information may be obtained from John A. Behnke, Associate Administrative Secretary, American Association for the Advancement of Science, 1025 Connecticut Avenue, N. W., Washington 6, D. C.

The reporting of leprosy is not required in New York State, although it is in New York City. Persons with the disease are not always admitted to the National Leprosarium. Occasionally, persons residing in endemic States move to New York when they learn that they have the disease, and a few patients have absconded from the leprosarium to that State. Information on many of these persons, however, is insufficient for analysis; the following discussion therefore relates only to patients originally admitted to the leprosarium from New York.

Of the 158 patients admitted from New York, 140 were of foreign birth and only 18 were born within continental United States. Of the latter, only 2 were born in New York.

From the available information concerning the American-born patients, the majority probably became infected before entering the State. One patient, however, almost certainly became infected in the State. He had lived in New York City until the age of 42 years (1923), when he visited in Italy for 3 months. On his return the disease was recognized, and he was sent to the leprosarium from the Immigration Station. The onset of the disease had occurred in 1921. Another patient may have become infected in New York. Born in Tampa, this patient moved to New York at the age of 6 years. There he lived with his aunt, who had moved to New York from Florida a year after she developed clinical manifestations of leprosy. The aunt was admitted to the leprosarium 6 years after moving to New York, and 9 years later onset of the disease occurred in the nephew.

Of the foreign-born patients, the greatest number, 59, were natives of the islands of the West Indies, and the next greatest number, 34, were natives of the countries of Europe. As in California, it seems likely that some of the foreign-born patients in New York contracted the disease after entry into this country. With 158 patients admitted to the leprosarium and many more not admitted, there has been ample opportunity for contact with infectious cases within the State. Nearly one-half (47.4) of the patients admitted were admitted more than 5 years after the onset of the disease; 17.5 percent, more than 10 years after onset. As shown

in the following tabulation, the length of time between entry into this country and onset of the disease was considerably longer for European-born patients than for patients born in the West Indies:

<i>Elapsed time (years)</i>	<i>Europeans: 24 (percent)</i>	<i>West Indians: 35 (percent)</i>
Less than 10-----	33.3	82.8
Less than 15-----	66.6	94.2
More than 15-----	33.3	5.7
More than 20-----	25.0	2.8
More than 30-----	8.3	0

Based only on the number of admissions to the leprosarium, the trend of the disease in New York is downward. There were 51 percent fewer patients admitted during the period 1936-53 than during the period 1921-35. Patients of European birth decreased 82.7 percent, and those of West Indian birth, 15.6 percent. Although the number of patients from Puerto Rico is small, patients native of this island increased 70 percent. Whether the apparent downward trend is actual or due to a decrease in the admission of recognized patients is not known.

Summary

Leprosy in the United States is a definite, though not a great, public health problem. The disease may occur in, and be transmitted in, any section of the country. Although a large proportion of the recognized cases have occurred in persons of foreign birth, a majority have occurred in natives of the United States. It must not be assumed, however, that all the patients of foreign birth became infected before entry into the United States, although a majority probably did. In the majority of American-born patients, the disease was contracted in this country.

A majority of the cases have occurred among residents of New York, Florida, Louisiana, Texas, and California, and most of the American-born patients have been natives of Florida, Louisiana, or Texas. The disease has been concentrated in restricted areas of Florida, Louisiana, Texas, and California. A number of patients recognized in the nonendemic States became infected in the endemic States.

A large number of persons were affected in outbreaks following attendance at picnics and similar social gatherings, but this may possibly be a reflection of the numbers who attended, as well as increased opportunities for consumption of food exposed at temperatures favorable for bacterial growth. Outbreaks following church socials included the familiar story of a typhoid fever epidemic following a church supper.

The number of outbreaks in summer camps was not large since all of them were reported by two States. None of the more serious types of foodborne or waterborne diseases, such as shigellosis, salmonellosis, and typhoid fever, were reported in this group in 1954. Outbreaks in labor camps were also few in number, possibly because such groups are not as numerous as some of the others listed.

The small number of outbreaks among passengers on trains, airplanes, or ships may be due in part to under-reporting since many patrons of dining services on trains and airplanes would have reached their destinations and would have scattered before onset of symptoms. On the other hand, the small number of outbreaks may also be a reflection of the attention given to dining car sanitation on trains and supervision of

food services on other interstate carriers (2). No outbreak was reported among patrons of railway dining cars, although one did occur among members of a dining car crew.

The outbreaks listed under the category of communities consist of those in which there was distribution of infected foods from bakeries and other retail stores to various persons in a community. They also include those in which polluted water caused illness in a community.

Waterborne Disease Outbreaks

In 1954, only four outbreaks were reported in which there was good evidence that water was the vehicle of infection. There were also three other outbreaks in which water was suspected as the source of infection.

One of the four waterborne outbreaks was typhoid fever in a coal mining village where water was pumped from a worked-out section of a mine into the distributing system of the town. Two outbreaks of gastroenteritis were reported. One was explosive and followed contamination of the water supply after heavy rains; the other occurred in a recreational area where untreated well water was used.

¹ Outbreaks on military establishments excluded.

² Includes single-case family occurrences.

Other outbreaks suspected of being waterborne included three of gastroenteritis following consumption of water of doubtful sanitary quality. Single cases of typhoid fever were also reported in which it was found that infection followed the use of water from wells. However, these are not included in table 2. Thirteen cases of gastroenteritis were reported among members of a basketball team who drank water from a school well which, on examination, was found to be polluted.

Milkborne Disease Outbreaks

The number of outbreaks in which there was definite evidence that milk or a milk product was the vehicle of infection was not large. In one instance, four persons in a family developed brucellosis after drinking raw milk from a cow that had aborted. The source of infection of six cases of typhoid fever in two families was traced to raw milk from a dairy farm where a carrier was found handling the milk. An outbreak of salmonellosis followed the consumption of eggnog in an institution. The person who prepared the eggnog was found to be a carrier of *Salmonella typhimurium*, the same organism that was recovered from the patients. Another outbreak in a hospital in which *S. typhimurium* was isolated followed the consumption of a food in which cheese was an ingredient. A group of five persons became ill with staphylococcal food poisoning following the consumption of ice cream. The chef who prepared the ice cream harbored *Staphylococcus aureus* in his throat, and he also had chronic paronychia on all fingers of both hands.

Nine persons in a family outbreak developed gastroenteritis after eating a food containing a cream cheese from which a gram-positive coccus was isolated. A staphylococcal food poison outbreak of about 100 cases was traced to ice cream. The ice cream mix had been allowed to stand at room temperature for several hours prior to freezing. Several cases of tuberculosis in children followed the consumption of milk from herds of cattle, in one of which 80 per cent were found to be tuberculin reactors.

Four outbreaks were reported in which milk

NOTE: Includes outbreaks reported on military installations. Includes outbreaks not shown in table 1.

season when these shellfish are known to contain toxic substances.

Two cases of poisoning were reported following consumption of tree tobacco (*Nicotiana glauca*).

Three outbreaks of chemical poisoning were reported. One outbreak of 160 cases followed the drinking of an acid fruit juice which had been stored overnight in a galvanized container. Another outbreak followed consumption of a soft drink which, on laboratory examination, revealed the presence of arsenic. Parathion poisoning in 10 laborers living in a migrant labor camp was suspected. One patient had signs of central nervous system involvement, but normal cholinesterase blood levels were found in all patients.

Trichinosis

Six outbreaks of trichinosis were reported in 1954 as compared with the 13 for 1953. The total (53) cases for 1954 was also similar to that (40) reported in 1952. In 1953, one large outbreak associated with infected hogs accounted for 73 cases, while the largest outbreak in 1954 involved 17 persons who ate sausage from two infected hogs which had been butchered by a friend. Three other outbreaks in 1954 were associated with pork products, and one was from the ingestion of bear meat. In one instance, grain fed hogs were implicated. The source of the infection was probably rats observed on the farm where the meat was obtained. In one State, some meat markets were found to be grinding beef without adequately cleaning grinders after grinding pork products. This practice may have resulted in at least one case. In each of the five outbreaks reported in 1954, examination of meat specimens revealed the presence of *Trichinella*.

Gastroenteritis

In 63 of the 103 outbreaks of gastroenteritis reported in 1954, there was not sufficient information from epidemiological reports to classify the etiological agent. For more than half of these, no food was available for laboratory tests, and for a large number no pathogens were isolated from the suspected food. For a few, no

bacteriological examinations were performed. Five of these outbreaks were probably of viral origin and may have been spread by person-to-person contact. An additional 13 outbreaks involving 489 cases were associated with various organisms. In three outbreaks, streptococci were isolated, and in a few, gram-positive cocci were isolated. In other outbreaks enterococci, *Escherichia coli*, paracolon and proteus organisms were isolated.

Of the total of 103 outbreaks, 68 resulted from food, 5 from water, and 3 from milk; for 27, the source was not found. Three outbreaks were associated with milk products. One waterborne outbreak was caused by drinking water that had been contaminated with flood waters.

A large proportion of the gastroenteritis outbreaks resulted from improper handling of food in restaurants and cafeterias. Some occurred in picnic and labor groups following the consumption of food left unrefrigerated for hours in the open. Many outbreaks were in private homes and schools.

In 1953, a number of outbreaks were associated with Government surplus stock turkeys. Although turkeys were responsible for a large number of outbreaks in 1954, none implicated Government surplus stock.

A large outbreak involving approximately 50,000 cases is not shown in table 3. This outbreak occurred in the general population of a metropolitan area. Extensive laboratory examinations were made, but the etiological agent was not determined.

Miscellaneous Outbreaks

Information was received regarding 10 outbreaks of diarrhea of the newborn which affected 140 infants and resulted in 27 deaths. In one instance, cases followed the return of a nurse who had been off duty 2 days with diarrhea. Two outbreaks occurred concurrently with numerous cases of diarrhea in the communities in which the hospitals were located. Overcrowding in the nursery for the newborn was considered as a contributing factor in one outbreak. Of the 27 deaths, 12 were reported to be in premature infants. In two outbreaks, *E. coli* were found in stool specimens.

Only two instances of laboratory infections were reported. In one, seven cases of endemic typhus fever probably resulted from inadequately sterilized equipment. A case of diphtheria developed in a laboratory technician who accidentally spilled a suspension of infectious material on her hands.

Information on 5 outbreaks of diphtheria was received from 4 States. Sixty-nine cases were reported, of which 25 occurred in and around a small town of 375 inhabitants. This was an unusually high incidence for an area of that size. In one State, the disease appeared among persons in older age groups, especially those housed in cheap transient hotels.

Streptococcal infections were reported by only two States. In one, there were 5 cases in a camp; in the other, 3 schools were involved and approximately 400 pupils developed the disease. In all instances, the disease was spread by personal contact.

An outbreak of arthropod-borne encephalitis was reported in the Rio Grande Valley of Texas during August and September 1954. It is estimated that about 600 cases occurred. The St. Louis type of virus was isolated from two fatal cases, and serologic tests also indicated this type of infection. In California, 96 laboratory confirmed cases of St. Louis encephalitis and 22 cases of western equine type of infection were reported in July through September. In 1952, 375 laboratory confirmed cases of western equine encephalitis and 45 cases of St. Louis type of infection were reported. In addition to these outbreaks, an unusually large number of meningoencephalitis cases were reported in Oregon.

Marsh gas poisoned 11 persons of a crew who were constructing a sewer line through marshy land. Poor ventilation in the trench permitted a sufficiently high concentration of gas to cause symptoms in some workers.

Epidemiological information was received on 34 outbreaks of infectious hepatitis. The infection in most of these outbreaks was considered to have been spread by person-to-person contact. No common source—such as food, milk, or water—was found in any of these outbreaks. Twenty-five of the total outbreaks occurred in schools and institutions, particularly institutions housing mentally ill patients.

Three outbreaks were among persons of low-income status. While the number of cases reported in epidemics was 1,315 in 1954, compared with 1,578 for 1953, the total numbers of cases reported weekly for 1953 and 1954 were 33,382 and 49,739, respectively. This indicates that many outbreaks probably were not investigated or reported.

The only outbreak of locally acquired infection reported was a group of four cases of malaria in one family. A high incidence of Cocksackie virus infections was reported in various parts of a State, and group B virus was isolated from many of the cases. Several hundred cases of an infection characterized by a purplish maculoannular rash was reported in one area, the etiology of which was not determined. Numerous reports on the epidemiological investigation of tularemia cases were received, all of which followed exposure to rabbits. Other reports included information on cases of ringworm, psittacosis, scrub typhus, mycotic infections, leprosy, Rocky Mountain spotted fever, brucellosis, anthrax, and leptospirosis.

Epidemiological information on 9 cases of human rabies occurring in 1954 were received, 3 from 1 State, and 1 each in 6 different States.

Only 2 instances of plague infection were reported in continental United States, and 2 in Hawaii. Each of these represent an isolation from rat fleas.

Information on 8 suspect cases of smallpox in 6 States was received. However, acceptable criteria for confirmation of diagnosis were lacking in each of them.

Although some outbreaks of poliomyelitis were reported, they are not included in this report.

There were no widespread outbreaks of influenza in the United States in the winter of 1953-54. Its sporadic occurrence has been reported by Davis (4).

Summary

This report summarizes the outbreaks and epidemiological information on unusual occurrences of diseases in the United States in 1954. Since outbreaks from common sources—food and water—appear to be brought more com-

monly to the attention of public health officers and to be investigated, reports on these outbreaks constitute a large part of the material presented here.

The relative frequency of the various types of disease outbreaks, by States, and the frequency of foodborne and waterborne disease in different groups of persons are discussed.

There is reason to believe that the reports received represent only a fraction of the outbreaks that actually occurred. Reports appear to be relatively complete in some States and poor or nonexistent in others.

An Important Date

Each month your health department and many hospitals, laboratories, schools, clinics, and homes receive a copy of PUBLIC HEALTH REPORTS, mailed to arrive on the 20th, or even earlier, depending upon geographic location of the subscriber.

Its pages carry timely research reports, analyses of current trends, new methods, concepts, and ideas, and topical reviews for the busy scientist, teacher, or public health worker. Capsule coverage of important public health meetings, like those of the American Public Health Association, help the PHR reader.

Not all our readers receive the journal on the delivery date. An official copy is trickled down to them through a series of other readers. Sometimes the trickle slows to a complete halt.

You can have your personal copy promptly. Use the subscription blank on the inside back cover. Let the 20th of each month be an important date for you, too.

Bicarbonates, sulfates, and chlorides of calcium and magnesium in water are appraised as a source of interference with the germicidal action of quaternary ammonium compounds at various temperatures.

Bactericidal Efficiency of Q.A.C. in Different Waters

By CECIL W. CHAMBERS, A.B., PAUL W. KABLER, M.D., Ph.D., ALTON R. BRYANT, B.S.,
LESLIE A. CHAMBERS, Ph.D., and MORRIS B. ETtingER, M.S.

INTERFERENCE of natural tap water with the bactericidal action of quaternary ammonium compounds (Q.A.C.) was first reported by Hanne, referred to by Lawrence (1), and has since been confirmed by other investigators: Public Health Service (2), Ridenour and Armbruster (3), Shere (4), Butterfield, Wattie, and Chambers (5), Humphreys and Johns (6), and others. This study was initiated to further determine and evaluate some of the causes of inhibition of Q.A.C. bactericidal action.

Experimental Methods

One ml. of *Escherichia coli* ATCC-11229 suspension was added to 99 ml. of water-germicide mixture to produce an initial bacterial density of approximately 100,000,000 organisms per ml. Test temperatures were thermostatically controlled at the various levels reported. At spe-

cific intervals, aliquots were transferred to Tween 80 Asolectin neutralizer, Weber and Black (7), from which duplicate portions were planted for agar plate colony counts. An experiment usually was made with 2 or 3 replicate test flasks for each germicide.

The method used was similar to the Weber-Black procedure (7) but differed from it as follows: (a) larger volumes were used to provide material needed for chemical control tests; (b) more than one test temperature was used; (c) bacterial suspension was prepared in phosphate buffered water instead of in test water; (d) suspension was filtered through sterile paper, eliminating most of the "freak jumps"; (e) suspension was stored in ice throughout a given experiment (this did not affect the test temperature as the ratio of suspension to test water was 1 ml. to 99 ml.); (f) culture was added to test mixture instead of test mixture to culture; (g) duplicate plates, using phosphate buffered dilution water, were planted in the range expected to yield 30 to 300 colonies; (h) initial and final numbers determinations were based on triplicate plates.

C. W. Chambers is in charge of the Bactericidal Agents Unit, Dr. Kabler is chief, Microbiology, Mr. Bryant is a bacteriologist, Dr. L. A. Chambers is director of research, and Mr. Ettinger is chief, Chemistry and Physics, Water Supply and Water Pollution Control Research, at the Robert A. Taft Sanitary Engineering Center, Cincinnati.

Controls and Compounds

Sterility control was maintained on all water, neutralizer, media, dilution blanks, and equipment used. It was inadvisable, due to the

breakdown of bicarbonates, to sterilize raw and tap waters. Controls indicated the presence of extraneous bacteria in some of these waters. Such contaminants, when present, were insufficient in number to affect the initial numbers determination at a dilution of 10^{-6} . These organisms did not result in germicide consumption, and they were killed during the waiting period allowed for the test mixture to come to constant temperature. However, when such contaminants were present on control plates, representative colonies were transferred to lactose broth to prove the absence of coliform organisms. Likewise, representative colonies surviving the longest exposure in germicide tests were transferred to lactose to exclude the possibility of counting extraneous noncoliform contaminants as *E. coli*.

The quaternary ammonium compounds used were: compound A—alkyl dimethyl benzyl ammonium chloride; compound B—para diisobutyl phenoxy ethoxy ethyl dimethyl benzyl ammonium chloride, and compound C—alkyl tolyl methyl trimethyl ammonium chloride.

Water Selection, Preparation, Measurement

Norwood, Ohio, well water was used in a considerable portion of this work because: (a) it was readily available; (b) previous studies (2, 5) had shown that this water interfered with Q.A.C.; (c) waters with an equal or higher mineral content are common on many dairy farms; (d) numerous municipalities, especially in the west and southwest, use waters with equally high or higher mineral content. The State health departments of Arkansas, Kansas, and Texas provided laboratory facilities, engineering services, and sample collectors, which enabled personnel associated with this project to conduct laboratory investigations in these areas.

Forty-five different types of well, tap, synthetic (distilled water with minerals added), softened, and sequestered waters were investigated. Tap and well waters were used fresh and unaltered, except when chlorine was present a slight excess of sodium sulfite was used for dechlorination. These waters were also investigated after being treated as follows: (a) boiled 2 hours, evaporation loss being restored with distilled water; (b) boiled, cooled,

and recarbonated with CO_2 , then decarbonated by shaking to adjust pH to the same level as that of the raw water before boiling; (c) stored at room temperature for 3 to 10 days; (d) lime softened; (e) partially softened by zeolite; (f) sequestered with either sodium hexametaphosphate (S.H.M.P.), tetrasodium pyrophosphate (T.S.P.P.), or the tetrasodium salt of ethylenediamine tetra acetic acid (E.D.T.A.).

In all experiments, any precipitate in the water was suspended by agitation while aliquots were being transferred to test flasks. Lime-softened water, in which removal of the sediment is an integral part of the process, was an exception to the preceding statement.

Results

Space limitations prevent the presentation of all data available. Results reported are considered representative of the more significant trends. With the exception of two tables, data obtained with long exposure intervals have been deleted. Findings are reported as percentages of bacteria surviving for a given exposure, based on the initial numbers determination as 100 percent.

A succession of individual experiments, constituting a series, were run with fresh, synthetic, or treated water. In a series using fresh and treated water, aliquots of treated water as well as those used unaltered were drawn from a common sample of fresh water. Most results reported are averages obtained in two or more series of individual experiments. Each series started with a new sample of water of a given type or, in the case of synthetic water, a freshly prepared batch. There was relatively little experimentation with trace elements and exclusion tests.

Calcium and Magnesium

According to Foulk (8), calcium and magnesium usually occur as bicarbonates in waters found in strata of the type bearing Norwood water. Therefore, the effect of these bicarbonates was investigated in natural waters and as the pure compounds produced in distilled water.

In tests with compound A in raw Norwood water, with a total hardness of 410 p.p.m. and

a combined calcium and magnesium bicarbonate content of about 350-375 p.p.m., marked interference with bactericidal action occurred (table 1). In this and all future references, bicarbonate alkalinities (regardless of attached ion), calcium salts, magnesium salts, and hardness are given as p.p.m. CaCO_3 according to reporting conventions of Standard Methods for the Examination of Water and Sewage (9). Additional results with raw Norwood water are presented in tables 4 and 5.

When an aliquot of Norwood water was boiled, precipitating the bulk of the bicarbonates as normal carbonates, the bicarbonate and hardness content dropped to 70 p.p.m. and 90 p.p.m., respectively, and interference was re-

duced from 8- to 25-fold at exposure intervals of 1 and 2 minutes (table 1). Recarbonation of an aliquot of this same water restored the interference. A comparison of results presented in tables 1 and 2 shows that pure calcium and magnesium bicarbonate in distilled water, in amounts equivalent to the total bicarbonate content of Norwood water, interfere to a degree comparable to raw Norwood water. In all instances rapid kills were obtained in distilled water with no hardness added.

The effect of several calcium and magnesium salts in distilled water, at concentrations equivalent to the total calcium and magnesium content of Norwood water, was investigated. These results indicated that, within the limits of the

methods used, there was little difference in the effect of the various salts (table 2). However, the interference of all these salts was significant at the concentrations tested.

Iron

In highly carbonated waters, iron occurs as the bicarbonate according to Foulk (8). Mueller and Seely (10) demonstrated interference with 10 p.p.m. of iron as Fe⁺⁺ ion at pH 4.0 or lower, but they indicated that above pH 4.0 hydrolysis occurs and interference disappears. However, in many farm dairy uses water is drawn and mixed with germicide before hydro-

lysis can take place. Therefore, information regarding the effect of iron in the native state should be of value.

Ferrous bicarbonate was produced and maintained in a closed system under nitrogen washed through 5 successive alkaline pyrogallol traps followed by 1 water trap. Experiments were run with 10 p.p.m. of iron as bicarbonate and, also, with a like amount as bicarbonate that was first oxidized by aeration until the test for Fe⁺⁺ was negative and a Fe⁺⁺⁺ test showed 10 p.p.m. Bactericidal tests in the presence of ferrous bicarbonate were made with oxygen free nitrogen streaming through the flasks,

above the test mixture, throughout the experiment. With ferrous bicarbonate, initial and final tests from each individual flask showed 10 p.p.m. Fe^{++} and 0 p.p.m. Fe^{+++} . The bicarbonate form was verified by titration. In experiments with ferrous bicarbonate, solutions were clear and colorless at the conclusion of tests. The results show that at pH 6.1 to 7.0 the interference of Fe^{++} is greater than that of Fe^{+++} (table 3).

Effects of Different Waters

Wyoming, Ohio, water originally has a total hardness of 520 p.p.m. and a bicarbonate content of 320 p.p.m. It is softened by lime-soda to a total hardness of 100 p.p.m. and a bicarbonate content of 60 p.p.m. Germicidal interference of this softened water was low, but restoration of the hardness by the addition of calcium bicarbonate resulted in marked interference. Control tests eliminated pH variations as the responsible factor.

Topeka, Kans., tap water was similar to that from Wyoming, Ohio, and likewise caused relatively little interference with compound B (table 1), but it did result in more interference with compound A than was true of Wyoming, Ohio, water. The boiling of Topeka water increased the interference slightly. In this case no mineral was precipitated, but the drop from pH 9.8 to 8.3 was probably a contributing factor.

Table 1 also shows the effect of Dermott, Ark., water (hardness 8 p.p.m. and total mineral content 252 p.p.m.) in which the major part of the mineral content is sodium and potassium bicarbonate (200 p.p.m.) and chloride (27 p.p.m.). Interference was very low in this water. To establish that this lack of interference was not due to the high pH (9.5), tests were run with 375 p.p.m. of sodium bicarbonate in distilled water at pH 7.5 to 7.9 in parallel with tests using raw Norwood water at the same pH. The results clearly indicated that sodium bicarbonate does not interfere under these conditions. These results also showed a marked difference between the interference in Norwood water and that of a synthetic water containing an equivalent concentration of bicarbonate as sodium bicarbonate.

Tests with Cincinnati, Ohio, tap water showed some interference at bicarbonate and total hardness levels of 33 p.p.m. and 94 p.p.m., respectively. Boiling had relatively little effect on this water in which a large percentage of the total hardness is permanent in nature. This is in marked contrast to Norwood water in which 90 percent of the total hardness is present as bicarbonate.

San Benito, Tex., tap water had a total mineral content of 1,150 p.p.m., of which 366 p.p.m. was hardness and a considerable portion of the latter was of the permanent type. Significant interference with germicidal action occurred in this water, and the interference was reduced somewhat by boiling.

Port Isabel, Tex., tap water had a total mineral content of 3,200 p.p.m. and 1,100 p.p.m. total hardness, mostly of the permanent type. This water represents the maximum interference ever encountered in studies with these compounds at the Robert A. Taft Sanitary Engineering Center (table 1). Boiling resulted in very little reduction of interference in this water, as might be expected, since permanent hardness is not affected by boiling.

Exclusion Tests

Norwood water contained a small amount of barium and strontium. No significant interference was noted in tests made with a mixture of barium and strontium bicarbonate in a concentration equivalent to the barium and strontium content of Norwood water.

Norwood water contained about 20 p.p.m. of silicon. Therefore, it was considered desirable to study the effect of this element in distilled water. Foulk (8) states that silica in underground waters is generally considered to be in the form of uncombined silicic acid. Accordingly, silicic acid was added to distilled water to produce a concentration of 20 p.p.m. as silica. The solution was initially adjusted to pH 10.0, using sodium hydroxide, in order to facilitate solution of the silicic acid. Storage overnight resulted in solution of the silicic acid while the pH dropped to 7.3. Because sodium hydroxide was used in the preparation of this water, it is probable that the silica was present as sodium silicate at the time the water was used in bacteriological tests. The ef-

the hardness to approximately 75 p.p.m. Additional data were obtained using varying amounts of E.D.T.A. without regard for alterations in hardness or pH. The addition of 0.3 percent E.D.T.A. further enhanced the activity of the Q.A.C. However, control tests indicated that 0.3 percent E.D.T.A. exerted a definite germicidal effect within 10 minutes but not within 2 minutes. Similar controls, with 0.2 percent E.D.T.A., established that there was no bacterial toxicity during a 10-minute exposure.

Data obtained indicate that at a concentration of 200 p.p.m. all Q.A.C. tested are reasonably effective at 37° C. in Norwood water containing 0.2 percent E.D.T.A. In similar tests at 22° C. the efficiency of compounds B and C was fair to marginal while that of A remained good. The latter was the only compound which showed good response at 10° C. in Norwood water treated with 0.2 percent E.D.T.A.

Discussion

The present study was concerned solely with the effect of the mineral content of waters on the bactericidal action of Q.A.C. Therefore, important public health considerations such as viruses, fungi, and the effect of factors like proteinaceous material, residual soap, and other foreign materials were not considered.

In the first part of this investigation, Q.A.C. concentrations were set at levels considered best for determining variations due to different types of waters used. Accordingly, results reported were not, in all instances, obtained under conditions best suited to an evaluation of the various germicides (13). The concluding work in this study was directly concerned with concentrations recommended for use. However, the scope of this investigation made it necessary to limit tests to three chemical types of Q.A.C.

Interference with germicidal action was generally high in waters having high concentrations of soluble calcium and magnesium salts. Any treatment which tended to precipitate, remove, or inactivate calcium or magnesium reduced the interference. Further evidence of the role of these salts was indicated by increased interference when boiled water was recarbo-

ated or calcium carbonate was added to plant softened water, followed by recarbonation.

Waters in which practically the entire mineral content was bicarbonates of sodium and potassium did not interfere. Boiling, which converted much of the bicarbonate to normal carbonate, did not significantly alter the interference pattern in such a natural water.

High mineral content alone did not necessarily result in high germicidal interference. Bactericidal results with Norwood and San Benito water were similar, although San Benito water has a much higher total solids content. The concentration of calcium and magnesium salts in these two waters is similar in quantity but different in type, occurring mostly as the bicarbonate in Norwood water and as the sulfate in San Benito water. This tends to confirm, in natural waters, the results obtained in synthetic waters, namely, that equivalent concentrations of various soluble calcium and magnesium compounds interfere to approximately the same degree. The nonhardness salts in San Benito water were those of sodium and potassium, and did not appear to have contributed to the interference. This finding coincides with the observations noted in tests with distilled water containing sodium bicarbonate, as well as in Dermott, Ark., water. Still further evidence in this regard was indicated by the significant reduction in interference in Norwood water partially softened by zeolite where sodium was substituted for calcium and magnesium.

The effect of temperature is marked, and the trend is similar to that reported by McCulloch and associates (14). At 10° C. all of the compounds at a concentration of 200 p.p.m. showed marked interference in Norwood water.

The analyses of Topeka and Cincinnati water were nearly identical insofar as hardness and alkalinity were concerned. Freshly drawn Cincinnati water interfered with germicidal action somewhat more than Topeka water. The difference in pH could be responsible for the different reactions in these otherwise similar waters. Ridenour and Armbruster (3), Mueller and Seeley (10), and others have shown that the activity of Q.A.C. is enhanced by high pH values. When Cincinnati and Topeka waters were boiled, the pH of Cincinnati water in-

creased while that of Topeka water decreased. This shift was accompanied by a slight decrease in interference in Cincinnati water while that of Topeka water increased somewhat.

Practical differences in the various methods of treating Norwood water were apparent. There was little difference in either the appearance or interference of the lime or partially softened zeolite-treated water at 75 p.p.m. hardness. Both treatments produced sparkling clear water. However, as a final rinse for utensils, lime or lime-soda softened water, due to the marked reduction in total dissolved solids content, should leave air dried glassware in a much more presentable condition than would be the case with zeolite-softened water.

Water treated with E.D.T.A. was clear while that treated with T.S.P.P. was very turbid. Since both of these additives, even though somewhat more effective than lime or partial zeolite softening in reducing interference, increase the total salt content of a water already high in dissolved solids, the effect on air dried glassware and equipment probably would leave much to be desired.

Summary

Many waters interfere with the bactericidal action of quaternary ammonium compounds. In this study hard waters have been shown to interfere seriously. Bicarbonates, sulfates, and chlorides of calcium and magnesium appear to be the primary cause of interference. Ferrous bicarbonate interfered to a moderate degree, but this interference was minimized when the iron was oxidized.

Natural waters in which the bulk of the mineral content was sodium and potassium bicarbonate did not seriously interfere with the germicidal action of Q.A.C. When such waters were boiled, most of the bicarbonates were converted to normal carbonates with no apparent change in interference.

Lime and partial zeolite softening removed a considerable portion of the interference from a hard water used in tests. Tetrasodium pyrophosphate and the tetrasodium salt of ethylenediamine tetra acetic acid reduced the interference of this water sufficiently to offer promise for use in practical applications.

An Experience in Home Injury Prevention

By HARRY WAIN, M.D., M.P.H., HAROLD E. SAMUELSON, M.P.H., and F. M. HEMPHILL, Ph.D.

AN EXPERIENCE in accident prevention in Richland County, Ohio, known as the home safety notebook project, sought to motivate families to keep a record of injuries in the home. It appears to have demonstrated that such families soon establish safety patterns that perceptibly reduce the rate of injuries.

The project was undertaken by the health committee of the Mansfield Parent-Teacher Association Council in cooperation with the home safety program of the Mansfield-Richland County Health Department. Two major purposes were (a) to test acceptability to home-makers of the methods used and (b) to measure change in frequency of injuries during a 16-week period. In addition, data on type of injury, location and activity of persons at the time of injury, parts of the body injured, and other injury characteristics were to be obtained.

The Mansfield-Richland County Health Department is 1 of 3 local health departments in the Nation carrying on a 5-year home safety program through a grant from the W. K. Kellogg Foundation. The home safety notebook project is one of many projects developed

during the course of this program, which was begun in the fall of 1951.

The Basic Plan

The recording by family members of all home injuries, regardless of severity, constituted the basic plan of action. The record was kept in a calendar-notebook, a booklet designed to facilitate the recording of selected information about each injury. The chairman and co-chairman of the PTA council health committee directed the project, and the chairman of each individual PTA health committee supervised the work of the participants.

The methods used in the project were modifications of those used in the home injury prevention experience conducted by the Washtenaw County Health Department of Michigan (1). In the Washtenaw County experience, public health nurses provided supervision and 95 families participated.

A total of 119 families agreed to keep safety records in the Richland County project. Ten or eleven families were selected from each of the PTA groups or mothers clubs in 10 elementary schools, and 14 families were from the health department staff. Participants were selected on the basis of agreement to cooperate and did not represent a random selection of families in the PTA or in the city.

Before the recording began, all PTA workers were given 1 hour of instruction in objectives and procedures by the health department home safety director. Following this orientation, each chairman visited the families in his group

Dr. Wain, who has been in local public health work in Ohio since 1939, is health commissioner of the Mansfield-Richland County Health Department in that State. Mr. Samuelson is director of the health department's community home safety program. Dr. Hemphill is associate professor of public health statistics, School of Public Health, University of Michigan.

and explained to a responsible member, usually the housewife, the objectives of the project, terms used, and procedures for keeping the record. Drills in filling in the notebook were held. The time for starting the records varied within different PTA groups, but all were begun within a 4-week period, in October and November 1953.

On cards furnished by the health department, the health committee chairman recorded the names, ages, and injury data for the families in their group. Approximately every 2 weeks, they contacted the families, by visits to the home, by telephone, or at PTA meetings, to secure or to give information about the project.

During the 16-week period, the health department's home safety director visited each family at least twice. These visits were intended to sustain interest and to secure con-

tinued participation, as well as to answer questions on procedures. The health department maintained close communication with the PTA workers and at various stages of the project sent mimeographed newsletters to the families.

The fact that no families withdrew from the experience indicates that there was substantial interest on the part of those participating. However, the records of 5 families were unsuitable for use in the tabulation of data. One family moved from the area; 1 family's record was destroyed during an intercity household move; 1 record was not usable because of a misunderstanding regarding the completion date; and 2 records were lost or misplaced.

The possibility exists that the family member who recorded the injuries was less conscientious in performing the task toward the end of the study period. However, for several reasons,

¹ One person had 8 injuries.

it is believed that the recording of injuries was faithful and continuous during the entire 16 weeks. As noted above, careful observation and close supervision were accorded the project throughout the period. Moreover, many families recorded injuries occurring outside the home as well as those occurring inside the home, and some families continued to record injuries during the several days between the end of the project and the collection of the records.

Conditions and Definitions

Certain conditions were inherent in the plan of this project, and selected definitions had to be imposed on the data in order to tabulate and summarize them.

Selection of the families to participate in the experience was without any known probability basis. Consequently, those selected do not constitute a statistical sample of known design, and there is no basis on which to assume that they were representative of the population of Richland County. In fact, certain characteristics of the participating families—age distribution, for example—would be expected to be at great variance from those of the county's population.

As shown in table 1, there were 244 males and 250 females in the 114 families whose records were analyzed, a male/female ratio of 0.976. This ratio is similar to that found in large population groups. The age distribution of the 494 persons, however, is notably unlike that of the general population in that there are far too few persons aged 0–4 years and 15–34 years. The person-per-family ratio was 4.3, which is well above the national average of 3.5.

Previous research studies of some 2,500 families in Washtenaw County, Mich., had indicated that rates of accidental injuries incurred within homes were relatively homogeneous by rural-urban and family income groups (1). These findings led to the expectation that rates for the Richland County families would simulate those for the Washtenaw County families if the following assumptions were made: (a) family constituency, living conditions, and other socioeconomic factors for the groups were similar; (b) the season of year in which the experiences were accumulated did not influence

the rate; (c) the groups were large enough to reflect the injury rate with relative accuracy; (d) conditions of instruction, motivation, and recording of events were essentially equal; (e) other pertinent factors were similar. Insofar as rates from this experience are found to parallel those from the Washtenaw County experiences, bases may be formed for acceptance or rejection of these assumptions.

Instructions on recording injuries included the following:

1. Record all injuries in the notebook provided by the health department.
2. Record all injuries occurring in your home or in other homes to members of your household, including relatives and others living with you.
3. Record the injury as soon as practicable after it occurs.
4. Give the best answer you can for each item of information requested and be as specific as necessary to be clear.
5. Refer all questions concerning the project to the PTA chairman of your group.

For this project, the term "home" was defined as the dwelling and yard area used for usual home activities. Not included within this definition are public and community playgrounds, parks, and buildings and areas used primarily for agricultural and vocational purposes. Several families recorded all injuries regardless of the place of occurrence, but because they gave the location clearly selection of the home injuries was an easy task.

Each injury was classified by the analysts as major or minor. A major injury was an injury having one or more of the following characteristics: (a) preventing usual activity for 1 hour or more; (b) costing \$1 or more for treatment; (c) receiving professional treatment. Any other injury was classified as minor.

Injury Frequency Patterns

Analysis of the recorded injuries by age and sex shows that males under 20 years of age exhibited approximately the same injury frequency pattern as did females in this age group (table 1). However, the male/female ratio of injuries for persons 20 years of age or over was

approximately 1:5. For all ages, females suffered about twice as many injuries as did the males.

The frequency of recorded injuries among both sexes was substantially reduced during the time of this project, as shown in table 2. The reductions after the first 2 weeks tended toward plateaus rather than regular decrements by time intervals. Graphically, these reductions resemble an inverted learning curve, suggesting that persons in this experience gradually adopted or learned safer ways of home life.

Table 2. Injury frequency data, according to week of participation

Week	Number of injuries, major and minor			Injury rate per person-year	Number of major injuries		
	Males	Females	Total		Males	Females	Total
1st.....	17	42	59	6.2	0	3	3
2d.....	10	24	34	3.6	0	1	1
3d.....	8	15	23	2.4	0	2	2
4th.....	9	15	24	2.5	1	1	2
5th.....	8	18	26	2.7	0	0	0
6th.....	5	18	23	2.4	0	2	2
7th.....	10	15	25	2.6	0	1	1
8th.....	9	12	21	2.2	1	0	1
9th.....	5	12	17	1.8	0	2	2
10th.....	8	10	18	1.9	1	0	1
11th.....	5	10	15	1.6	0	1	1
12th.....	3	11	14	1.5	0	2	2
13th.....	4	6	10	1.1	1	0	1
14th.....	2	11	13	1.4	0	1	1
15th.....	5	8	13	1.4	0	1	1
16th.....	8	4	12	1.3	2	0	2
Total.....	116	231	347	2.3	6	17	23

During the first week of the project, injuries were recorded at the rate of 6.2 per person-year. This rate is comparable to the estimated rate of 6.0 in the Washtenaw County research studies and to the rate of 5.5 reported for the week before the recording of injuries began in the county's 95-family experience. Furthermore, the reduction in rate of reported injuries among the Richland County families from 6.2 during the first week to 1.3 during the sixteenth week parallels the change from 6.1 in the first month to 1.2 in the fourth month among Washtenaw County's 95 families.

Not ascertained.....	1	2	3
Total.....	116	231	347

These similarities in rates are very impressive. The experience in Richland County indicates that interested leaders of club groups with a relatively short period of training and with little expert supervision can make noteworthy contributions in the field of home accident prevention. It also indicates that the home-recording technique might be used profitably on a broad scale within a health jurisdiction by enlisting the cooperation of community organizations.

If injuries had continued at the rate of 59 per week, as during the first week, a total of 944 injuries would have accumulated. The 347 recorded are approximately 600 fewer than might have been expected. Of the 347 recorded injuries, 23 were classified as major injuries. If these had continued at the rate of 3 per week,

as during the first week, 48 would have been recorded, or at the rate of 8 recorded for the first 4 weeks, 32 would have been reported.

The infrequency of major injuries among the families in this experience argues against drawing any conclusions from the data on these injuries. There appears, however, to have been a trend for reduction in major injuries during the same time that minor injuries were being reduced, at least among the females. Since descriptions of accidental injury occurrences rarely allow accurate prediction of the severity of the injury, programs of prevention may well be aimed at the often recurring events which terminate in minor injuries with the expectation that the number of severe injuries will be reduced concurrently.

Injury Characteristics

Table 3 shows the location and type of activity when injuries were incurred. Predominance of injury to females was accounted for almost exclusively by "preparing meals" and "household tasks" and by location in the kitchen and dining room and on steps. At another season of the year, the yard might be expected to present a higher relative frequency of location, as was the case in the Washtenaw County research studies, and the entire pattern for males might be changed.

Males suffered injury most frequently during the hours of 11:00 a. m. and 1:00, 4:00, and 5:00 p. m. The frequency among females was greatest from 10:00 to 12:00 a. m. and from 4:00 to 8:00 p. m. (see chart). The variations in injury occurrences by hour of the day and by

age and sex groups suggest concentration of preventive effort at specific hours for the different groups. Children under 10 years appear to be injured during the afternoon and evening far more often than during the morning, and the times of highest frequency for adult females appear to be associated with the usual hours of meal preparation or other routine household tasks.

Cuts were the predominant type of injury, and bruises were next in importance (table 4). Burns from hot surfaces occurred approximately six times as frequently among females as among males. Cuts occurred most frequently among adult females; among males, children suffered cuts more frequently than adults. Children of both sexes suffered many more bruises than did their parents. These data provide suggestive bases for specific approaches to prevention, as well as indications for advice regarding first-aid practices.

The upper extremities, especially the fingers and the hand, suffered injury most often (table 5). Tabulations not presented in this paper showed that the injuries to these parts were largely cuts, with bruises and burns next in order. The majority of the difference between the number of injuries to females and the number to males was accounted for by injuries to the fingers and hands.

Table 5. Number of injuries in males and females, according to part of the body injured

Part of body	Males	Females	Total

Responsibility for the injury was attributed to the injured person for 77 percent of the injuries to females and for 67 percent of those to males (table 6). Assignment of responsibility for an accidental injury is, of course, a difficult task. Adults and older children were usually considered responsible for their own injuries. For 24 injuries to children, the mother was

listed as the person responsible, but only one father was thus implicated. Both parents were responsible for 6 injuries to children.

The most common action taken when females were injured was "change in performance of household task"; for males the most frequent action was "safety instructions to person injured" (table 7). A nonspecific category composed of such terms as "being more careful" and "being more thoughtful" was recorded for 19 injuries to males and 50 to females. "Correction of environment" was recorded for 43 of the 347 injuries. These data suggest that about 90

Table 7. Number of injuries in males and females, according to action taken to prevent similar injuries

Action	Males	Females	Total
Safety instructions to person injured.....	34	36	70
Safety instructions to self (when injured).....	1	8	9
Safety instructions to others than persons injured (as well as to person injured).....	6	3	9
Correction of environment.....	12	31	43
Change in performance of household task.....	21	68	89

More than one action.....	0	1	1
Nothing.....	13	22	35
Not ascertained.....	6	9	15
Total.....	116	231	347

percent of the injuries could be attributed to practices and personal action, since for only 12 percent was the environment changed. However, the data may indicate that few persons in the home are capable of interpreting the role of environment in accident causation and of making environmental changes for prevention of injuries. The records showed that most participants seriously attempted to provide information concerning action taken to prevent similar injuries, and perhaps the recording of such information helped in developing safe practices and improving the safety of surroundings in the home.

Summary

In a home accident prevention project in Richland County, Ohio, the rate of injuries per person-year for 114 families was reduced from 6.2 during the first week to 1.3 during the 16th week. This finding, which parallels the reduction reported in a similar project in Washtenaw County, Mich., suggests that the recording of injuries by families may be a method useful in establishing safety patterns in the home, as well as in collecting epidemiological data.

Co-sponsored by the Mansfield-Richland County Health Department and the Mansfield Parent-Teacher Association Council, the project demonstrated a cooperative approach between an official health agency and a civic organization. The fact that no families withdrew indicates that interest in the project was sustained throughout its course.

The procedures used were both economical and practicable and could be applied in any community. They might be used profitably on a broad scale within a community or health jurisdiction.

The data obtained concerning several characteristics of accidental home injuries add to the steadily accumulating information on this problem. Such data are essential for sound planning and operation of home accident prevention programs.

| *Local health officers are offered an idea that may strengthen nutrition education for food buyers at the "point of sale."*

Nutrition at the Shopping Center

By WILLIAM H. SEBRELL, Jr., M.D.

THE nutritional quality of diets in this country has improved steadily since World War II. Yet there are further opportunities ahead. Just because we can say that the average man in the United States today obtains enough food to prevent serious deficiency disease does not mean that he is obtaining enough food of the right kind to give him optimum health, to help his children grow at their best rates, to prevent chronic disease, to protect him against the added stress of a severe illness, or to give him the extra stamina needed to produce to capacity in today's intensely competitive world.

We do not have widespread serious deficiency disease any more—but this is no reason to be complacent. Let's look for a moment at a form of malnutrition that affects at least a quarter of our population. I refer to obesity. Health officers and physicians are waging a ceaseless war against this condition.

Sellers of food, too, have a very real interest in this form of malnutrition as well as all other forms—not only a humanitarian interest, but a business interest. The fat man is fat because he eats too much; the remedy is to get him to

reduce his calorie intake until he uses up his own excess fat. Is it better business to sell him 3,500 calories as 2 pounds of sugar or to reduce his calories to 2,700 by selling him 2 pounds of sirloin steak? Or to look at the problem from another angle: If he is seriously overweight, he may die as much as 10 years earlier than he would if he were normal weight.

Common Nutrition Deficiencies

Many remember the food business in the southern States about 25 years ago, when deficiency disease was widespread and the nutritionally sick and incapacitated largely bought molasses, grits, fatback, and collards. Compare that with the food business of the south today. Florida has become one of the great cattle raising States. We see increased livestock and dairy farming and more fruit and vegetable production all over the south.

One of the greatest needs today is better nutrition education. In a survey by General Mills (1), covering nearly 60,000 children in 38 States, it was found that diets tend to become poorer as children grow older; that 52 percent of high school girls' diets were poor; that the diets of boys were notably deficient in fruits and vegetables; that the adequacy of the child's diet relates closely to the occupation and economic status of the parent; and that adolescent girls drink far too little milk in the belief that it is fattening.

Dr. Sebrell, director of the National Institutes of Health, Public Health Service, presented this paper, condensed here, at the National Food Conference, Hollywood, Fla., March 3-6, 1955.

In a study by the agricultural experiment stations of six northeastern States (2), conducted in 1952, the diets of pregnant women, industrial workers, and students from kindergarten through colleges were judged by the same standards. The most common and serious deficiency was vitamin C; deficiencies in calcium and vitamin A also occurred frequently. In a 5-year Iowa statewide project by Dr. Eppright of Iowa State College (3), a deficiency of calcium and vitamin C was found. Most conspicuous for poor diets were the teen-age girls—a situation cited as particularly alarming because of its potential effects on the next generation. In New York State, Trulson (4) examined 3-day diet records of 10,000 children, half of them in the fourth and half in the tenth grade, and found the poorest food practices among the older girls.

Another group suspected of prevalent nutritional inadequacy is the older population, people over 65—a group which has increased twice as fast as the total population since 1900. Nutrition science, using new biochemical approaches, offers much promise against the diseases of the later years. In the aged, poor diets may result from psychological, social, or mechanical difficulties. About four-fifths of this age group live with relatives. At the family table, the aged may be handicapped by dental and digestive difficulties, and even their status with the family may affect their diet. Sometimes their nutrition is poor because of habits acquired in early life. These habits are not easily changed, and their modification must be approached with caution. Wisdom, tact, and patience are needed to promote good nutrition in this group and must be applied in all educational programs, whether the physician, nutritionist, or a public advertisement conveys the information.

Education in the Food Store

Nutrition education is the essential link between professional knowledge and the improvement of food practices. It seeks to establish public understanding of, and demand for, a food supply adequate for optimum health—a balanced consumption of nutrients—taking into account a wide range of incomes. The physi-

cian, the nutritionist, the health officer, the scientist, and the teacher are struggling with limited resources and limited opportunity to teach good nutrition to the individual.

The housewife learns from these sources that good nutrition can help make her pregnancy successful, her baby healthy, and its growth good—that health, vitality, and long life are not attainable without good nutrition. It is usually her responsibility to buy the food for her family. And where does she make this final day-to-day decision? Frequently in the food store and the market. And what guidance does she get at the point of sale to help make her purchases fit with what she has been taught? None. And what help does she get to satisfy her that she is carrying out her responsibility? None. She is faced with a new set of values as she walks through the market deciding what she will buy—a comparison of prices, of sizes and weights, of quality, beautifully, colorfully, and as effectively done as modern sales techniques can do. But she receives no guidance whatever.

Let me point out where we have failed. I have just mentioned the extensive studies that have shown deficiencies in vitamin C, calcium, and vitamin A. Most food sellers would know what foods to tell families to buy in the store to combat these deficiencies. But they are missing a great opportunity for using that knowledge.

Many millions of dollars every year go into the pockets of food faddists with special food items to sell—items that may range from dried seaweed to blackstrap molasses supposed to possess extraordinary food values of some kind. The success of the food faddist in recent years is an indication of our partial failure in sound nutrition education for the general public. The food faddist's methods are insidious, yet effective. As a lecturer, a pamphleteer, a propagandist, he sells the story that the American diet is deficient, that many common foods are harmful or dangerous, that malnutrition is widespread, that most of us suffer some ailment as a result, that we must radically change our diets to regain health and to avoid disease in the future—and, of course, we must use plenty of his special food items.

It is hard to believe that so transparent an argument could be successful, but it has been.

The regulatory agencies such as the Federal Trade Commission, the Food and Drug Administration, and the Post Office Department are doing what they can to control false and misleading advertising. But the only permanent answer is a planned education campaign—one that teaches by truth, logic, and repetition the correlation between food, nutrition, and health.

If we could educate the people in the fundamentals of good nutrition, they could be led to spend their money on good food in the market and on proper dietary supplements that would do them the most good.

Many outlets are now being used to good purpose, but we are failing to use one of the best avenues for putting the message across where it really counts—where food is displayed and sold.

We will never have a really successful program until the food sellers and the food industries cooperate with the scientists, nutritionists, and teachers in developing a positive, aggressive, coordinated program to present basic nutrition facts clearly and simply to the Amer-

ican housewife, so that she can use those facts at the point of sale for the best nutrition for her family.

I am sure that if some such plan could be evolved it would prove to be good business practice and at the same time make a significant contribution to public health.

Housing Rehabilitation in Disasters

The Department of Health, Education, and Welfare has recently developed jointly with the American National Red Cross a plan by which commissioned engineer officers of the Public Health Service will assist the Red Cross in emergency housing rehabilitation activities at times of natural disasters.

Red Cross rehabilitation of buildings damaged by disasters requires on-the-spot assessment of the damage, estimates of costs of restoration, preparation of specifications for restoration, arranging for bids from contractors, and inspection and certification of the contractor's work. The Red Cross maintains a permanent staff of 10 regional building disaster experts, plus a small reserve. The Public Health Service will at times of disaster assign to the Red Cross reserve sanitary engineer and sanitarian officers competent in the

housing field. A few regular officers also will participate. All reserve officer participation will be on a voluntary basis.

The Public Health Service will develop, as a "housing component" of its inactive engineer reserve, a group of from 50 to 70. Approximately 20 will be selected for assignment to a 10-day training course in August 1955 on housing construction, cost estimating, and Red Cross policies and procedures. All members of the housing component of the reserve will periodically receive information on the subject of emergency housing rehabilitation from the Red Cross and Public Health Service. Also, additional training courses will be provided.

The Red Cross will pay all travel and per diem costs for participating PHS officers for training or for disaster relief work.

Practical Problems in Rabies Control

At the annual meeting of the American Public Health Association in Buffalo, October 11, 1954, the Conference of Public Health Veterinarians held a panel discussion on recent advances in rabies control. Current methods and problems in rabies control were touched on through a simple and effective device which gave the discussion unity—the story of the prevention of an imaginary rabies outbreak in an imaginary country. The essentials of the discussion follow.

KOPROWSKI: The events forming the basis for discussion during the present session occurred in June 1954 in the State of Simona of the Republic of Neutralia. I may add that Neutralia (with thanks to Evelyn Waugh) is imaginary and composite and represents no existing nation.

Two large dogs attacked a group of 13 children returning from school. Although all the children came into contact with the animals, some suffered only minor wounds or scratches, while severe wounds of the head and neck were inflicted by the biting animals on other children. Passersby and school teachers, alarmed by this savage and unprovoked attack, called police. Several policemen appeared on the scene immediately, and, as Neutralia permits the carrying of firearms, one of the men shot one of the biting dogs through the head because the animal could not be subdued. The other dog was taken into custody.

Before we start our discussion of these events, I would like to acquaint you briefly with the State of Simona. It comprises an area of 45,000 square miles of land and about 1,500 square miles of inland water.

Farm acreage accounts for about 65 percent of the land area, and

many farm and domestic animals are kept, including large stocks of dairy cows. In the 25 percent of the country covered by dense forest, there is an abundance of wildlife—foxes, coyotes, beavers, wolves, deer, and so forth. Bats are also quite prevalent in this woodland as well as in the inhabited parts of the state.

Simona has a democratic, progressive government and a well-organized department of health and animal husbandry in the capital. The population of 12 million inhabitants is known for its fondness for domestic pets, particularly dogs, and there is, therefore, a large dog population.

Simona was supposed to be free from rabies during the period 1946–54. However, in all adjoining territories, and particularly in the neighboring State of Granchester, the disease had always existed in enzootic form so that the danger of infection being introduced was constantly present.

Now, after giving you this incomplete and sketchy information concerning the State of Simona, I would like to return to the accident which befell the children and ask the members of the panel some questions.

Did the policeman who shot the dog through the head act wisely?

What should have been done with the living dog? Dr. Tierkel?

On Clinical Evidence

TIERKEL: It's too bad the policeman shot the dog through the head. He should have shot him through the heart since shooting through the head damages the brain and makes it less useful for diagnosis. The dead dog's head should be sent to the laboratory for examination for Negri bodies.

If it is possible to capture the biting animal, the apprehended dog should be watched for 7 to 10 days by a qualified observer to see if the animal shows clinical signs of rabies.

Most important, the captured dog should be allowed to die a natural death from the disease if he has it in order to increase the chances that his brain, on examination, will disclose fully developed Negri bodies.

The head should be removed, packed with ice in a watertight double container and sent to the public health laboratory by the fastest means of transportation. It should not be frozen because freezing often distorts and tears the structure of the tissues, making the examinations difficult.

Panel Members

Moderator of the panel discussion on rabies control was Dr. Hilary Koprowski. He is assistant director of viral and rickettsial research for the research division, American Cyanamid Company, Pearl River, N. Y.

The panel members were: Dr. Donald J. Dean, veterinary consultant, New York State Department of Health; Dr. Leland E. Starr, public health veterinarian, Georgia State Department of Public Health; and Dr. Ernest S. Tierkel, director, Rabies Control Activities, Communicable Disease Center, Public Health Service, Atlanta.

Also participating, toward the close of the discussion, were Dr. John P. Fox, professor of epidemiology, department of tropical medicine and public health, Tulane University of Louisiana School of Medicine; and Dr. T. F. Sellers, director, Georgia State Department of Public Health.

Of course, absence of Negri bodies in the brain does not conclusively prove that the dog is free from rabies. If there are no Negri bodies, one grinds up samples from various parts of the brain in a 10 percent suspension and injects this into the brains of mice to see if these test animals will become infected.

In practice, 10 to 15 percent of routine Negri-negative canine brains turn out to be positive on the mouse tests. It's a good idea to do a general autopsy of the dog but not if it delays shipment of the head to the public health laboratory.

Another point—the submaxillary salivary glands should be dissected from the head and shipped to the laboratory so that a test can be made for the presence of rabies virus in the saliva. Again, that is done by inoculation of a 10-percent suspension of the salivary glands into mouse brain. To preclude other encephalitides, a serum neutralization test is made with the virus isolated in mice. This procedure definitely establishes whether rabies is present.

DEAN: Fifteen to twenty-five percent of the dog heads examined annually in upstate New York prove rabid. Diagnosis is made in 95 to 98 percent of the rabies cases through finding typical Negri bodies in impression smears or sections of

the dog's brain. The remainder are established as rabid by mouse inoculation tests. All street virus strains isolated in New York State to date have been *negrigentia*. Fixed rabies strains, on the other hand, early lose the ability to produce Negri bodies.

KOPROWSKI: Some African strains of rabies virus do not elicit formation of Negri bodies.

DEAN: Another problem in diagnosis is the presence of inclusions similar to Negri bodies when rabies doesn't exist—false positives. These structures are artifacts or inclusions associated with other viral diseases. They are particularly common in cats and raccoons. This is important since with hyperimmune antirabies serum decisions on human treatment have to be made earlier.

KOPROWSKI: The necessary steps, then, in determining whether rabies is present in a biting animal may be briefly outlined:

First, a period of observation by a qualified observer.

Second, general autopsy when the animal dies or is killed following clinical signs of rabies, with the use of good pathological procedures.

Third, shipment of the head, packed in ice but not frozen, to a suitable laboratory; or shipment of brain tissue and salivary glands, in glycerol-saline solution.

Fourth, laboratory diagnosis with (a) proper staining to reveal the pathognomic Negri bodies, which are sometimes hard to differentiate from nonrabies inclusions; (b) the inoculation of mice with brain suspensions which have been treated with penicillin or streptomycin, the observation of mice for sickness or death, and the examination of mouse tissues for Negri bodies; and (c) accurately performed serum neutralization tests.

Following these procedures, one of the biting dogs in Simona was diagnosed as suffering from rabies, and in all probability his saliva at the time of the attack upon the children was infectious. We shall return later to the outline of treatment of the children.

Meanwhile, we have to report regretfully that within 2 weeks several more confirmed cases of rabies in dogs were reported from other areas of Simona. After that the spread was rapid, and the disease was not confined to dogs. By the end of September the following cases of rabies had been recorded: 79 dogs, 14 cattle, 8 cats, 2 horses, 3 sheep, 7 foxes, and 1 deer. Almost all counties of the state were affected. What control methods were to be adopted by the State of Simona Public Health Department?

On Dog Vaccination

DEAN: There are two problems: canine rabies, to be solved by vaccination and dog control, and the more complex problem involving rabies in wildlife and farm and domestic animals other than the dog.

Dog control should obviously be tightened although this is difficult to achieve in rural areas. One should next vaccinate as many dogs as possible so as to impose a barrier of immune dogs between infected wildlife and man. Experience has shown that if 70 percent of the dog population is vaccinated, rabies can be controlled.

Two effective vaccines are available. One contains killed virus produced in mammalian brain tissue; it will afford protection for 1 year.

The other, the Flury strain of modified live virus rabies vaccine, produced in embryonated hen's eggs, protects for 4 years, and possibly for life. We have had extensive field experience since 1946 with both types of vaccine.

In upper New York State, where wildlife rabies is endemic in approximately one-third of the area, and where 314 to 1,175 laboratory confirmed cases have been reported annually since 1944, canine rabies has been dramatically controlled since the dog program was initiated early in 1946. We had 233 rabid dogs in 1944, 503 in 1945, and 377 in 1946, the year our control program started. Since then we have had only 16 to 48 annually despite the widespread and continuing wildlife infection.

From 1946 through 1949, brain tissue vaccine was the only product available for rabies prophylaxis. Its use declined during 1950 and 1951. In this period the attack rate for nonvaccinated dogs was 3 to 11 times as great as that for dogs vaccinated with killed virus rabies vaccine.

The modified live virus vaccine was first used in two of our counties in 1950. Its use grew steadily. It has been the only vaccine used in all county vaccination programs since 1952.

The greatest advantage of the modified live virus vaccine is that it confers more profound and more enduring immunity than the killed virus product. We have had fewer vaccination failures.

Of the rabid dogs reported in upstate New York since the rabies control program started in 1946, 82, or 13 percent, of the dogs were previously immunized with brain tissue vaccine. Of these animals, 52 died of rabies more than 1 month but less than 3 years after vaccination. In contrast there have been only 2 vaccination failures and 1 vaccine death among the 200,000 dogs that have been given the chick embryo product.

It is more effective and cheaper to vaccinate individual dogs every 4 years. Successful annual vaccination is difficult to achieve, particularly in areas where rabies does not exist or where infection is minimal.

Another advantage of modified live virus vaccine is that it appears to be safer for injected dogs. Most of us have witnessed untoward neurological side reactions in occasional animals given the killed virus vaccine. In the absence of controlled studies the exact incidence is unknown, but it is probably in the order of 1 to 3,000 or 1 to 5,000 animals injected.

It should be said, however, that many practicing veterinarians have vaccinated thousands of dogs with brain tissue vaccine without observing serious untoward effects. In our experience, neurological side reactions attributed to modified live virus vaccine have been limited to the death of 1 young puppy and 1 cat.

TIERKEL: Puppies should be vaccinated as early as 2 months of age, and they should be revaccinated at 1 year of age.

Two other countries besides the United States have done mass vaccinating with chick embryo vaccine, Israel and Malaya.

In Israel the jackal was the wild animal vector. Israel, like Simona, is surrounded by rabies-infected countries.

Israel got rid of rabies when it vaccinated all dogs and reduced jackal populations by poisoning campaigns.

Malaya was not able to get rid of rabies over years of trying phenolized, killed vaccine in local areas. But now that the country has carried out a well-organized national campaign with chick embryo vaccine, rabies has been wiped out.

On Registration and Licensing

KOPROWSKI: Now that we have discussed vaccination, we should take up the problem of registration and licensing of dogs as one of the methods of control.

TIERKEL: Registration and licensing of dogs is not the most important rabies control measure. It is basically a method for financially supporting rabies control work. It identifies the animals in the community and gives owners a sense of

responsibility for their live property. Many areas make vaccination a prerequisite for a license. Still others combine vaccination and licensing in a single operation. The latter is ideal because it entails only one trip for the dog owner, one clerical operation all around.

DEAN: We favor permissive county legislation making vaccination a prerequisite for licensing in rabies-infected areas or in areas adjacent thereto. We agree, however, that effective rabies control can be achieved without linking vaccination to licensing.

STARR: In Georgia we have no State licensing of dogs, but Atlanta has had dog licensing as a city. In Atlanta dogs are vaccinated when they are licensed. However, the number of dogs licensed has been too small to reduce materially the incidence of rabies.

In 1952, vaccination clinics were set up by the city health department at a cost of \$1 a dog, but the response was disappointing. Then in 1953, in desperation, the county paid the whole cost and made dog vaccination free. We put on a big ballyhoo—radio, television, loudspeakers on trucks. The veterinarians vaccinated their usual number, but the dogs came in. There are some things I don't like about free vaccination, but it got the dogs in.

On Roundup of Strays

KOPROWSKI: What should be done about stray dogs?

STARR: Rounding up stray dogs requires shelters, rolling equipment, staff. It is a public health problem.

TIERKEL: The roundup of dogs is a public health problem; it should be carried out by dog control men in uniform who are regarded as members of public health teams, not by dogcatchers who are regarded as looking for fees. The dog control men might also be invited to talk to school children on the diseases of dogs, proper care of pets, and importance of rabies control.

STARR: There is a big stray dog problem in Georgia. People have

lots of dogs, but they won't take responsibility for them. It's their dog until they have to vaccinate it.

In Atlanta about 12,000 dogs are always inoculated by private veterinarians. These are well-kept dogs which probably don't have rabies anyway. When dogs are rounded up for vaccination, the irresponsible owners hide their dogs when the truck comes along. They will, however, bring their dogs for vaccination if it's free. When dogs were finally vaccinated free in Atlanta in 1954, there were all kinds of dogs, ill-nourished, diseased, mangy dogs, dogs which should have been destroyed, but what can we do?

There is also a wild dog problem in Georgia—packs of wild dogs running around. The solution to the wild dog problem is to get people interested in getting rid of them.

KOPROWSKI: We want to talk later about wildlife rabies. Before that, I would like to ask whether the panel thinks leashing laws are effective? Dr. Dean?

DEAN: Leashing laws are needed in heavily populated areas to protect the public against dog nuisances. Leashing laws are important whether rabies exists in the area or not. The restraint of dogs, however, is not the most important aspect of rabies control. For example, only 10 percent of the rabid dogs in up-state New York are strays.

KOPROWSKI: Two other points should be mentioned in connection with rabies control in dogs. They are: first, the compulsory reporting of suspicious symptoms and deaths of animals, and, second, the building up of a good diagnostic service.

I think that all members of the panel agree that these are important parts of the framework of a rabies control program. But there is another very important part—the reduction of rabies in wildlife.

On Wildlife Control

DEAN: Wildlife control is the third and most difficult leg of a rabies control program. (First is dog vaccination, second is dog control.) Our knowledge of rabies in wildlife is

scanty. Reporting in wild animals is improving but is obviously sketchier than reporting in dogs and cattle. In New York State we have had rabies in dogs since the early colonial era, but only recently have we recognized the disease in wildlife. We do not think that the upsurge in wildlife rabies is just a matter of better reporting. We think there has been an actual increase. Just why is the \$64 question.

Wildlife rabies has a bizarre epidemiological and geographic pattern. For instance, skunk rabies is endemic in Iowa but appears to be spreading to other areas, such as the Dakotas. In the northeastern States, the fox is the principal vector of rabies.

In New York we know that wildlife rabies not only rises and falls with fox populations but also that foxes can be thinned out by trapping, bounty payments, and poisoning. Experience suggests that reductions of the fox population to one fox a square mile will reduce vulpine rabies. Present techniques for controlling wildlife, principally trapping and den gasing, are too expensive for widespread economical use.

Poisoning offers hope for the future, but there is the problem of species selectivity. After all, one does not want to poison dogs and domestic animals indiscriminately and to expose children to unnecessary hazards. Our conservationists are actively exploring the use of species selective baits. We confidently believe that our canine rabies problem will disappear once wildlife rabies has been eradicated.

STARR: Trapping certainly works, especially if you have dog vaccination too. But you must have community support. In one Georgia county we poisoned. Cattlemen put out eggs, hamburger, and wieners with strychnine. The bait disappeared, but we didn't find any dead foxes.

Pennsylvania spent \$116,000 poisoning in 16 counties. The incidence of rabies fell, but we don't know whether the poisoning did it or not.

KOPROWSKI: There is something important to rabies control, both in wildlife and in domestic animals,

which we haven't touched upon, and that is publicity. The public must be kept informed of its responsibility.

The rabies control measures which have been described may be summarized briefly as follows:

First, the vaccination of at least 70 percent of the dog population, compulsory if necessary, since other control measures without vaccination have proved unsatisfactory.

Second, elimination of strays through registration, licensing, and restraint of dogs.

Third, reporting of suspicious symptoms and deaths and the building up of adequate diagnostic services.

Fourth, the reduction of wildlife species by poisoning, trapping, shooting, and so forth.

Fifth, a publicity campaign designed to make the public aware of the importance of the above measures.

On Vaccination of Animals

KOPROWSKI: Now, I would like to have the members of the panel discuss briefly the vaccination of animals other than dogs, chiefly cats and cattle, since they, too, were involved in the epidemic in Simona.

TIERKEL: We didn't include cats in our mass vaccination programs. Private owners can vaccinate cats. We find that rabies in cats disappears when dog rabies is under control.

DEAN: This is undoubtedly true where only canine rabies exists. Our experience indicates that cat rabies is associated with the disease in foxes.

KOPROWSKI: What about the vaccination of cattle?

STARR: Loss of cattle as a result of rabies was so heavy in Georgia that the State legislature considered free vaccination of cattle.

We tried chick embryo vaccine on test herds. On the last round, we inoculated 19 herds in a rabies endemic area, leaving 25 percent unvaccinated for controls (1,107 animals inoculated in all), but since none of the animals were attacked

smaller segments of time, the minimal period can be determined.

Time must be accurately recorded. In most time studies, the starting time and the total time for each activity are recorded in appropriate columns. Although this technique is satisfactory, the Yale project found that a time bar was simpler for participants to use and worked just as effectively.

Participants must code their own activities. Theoretically, it would be better for participants to record their activities in narrative form and for the research staff to code the activities. In practice, however, it proved impossible in the Yale project to secure narrative time logs from most public health workers in sufficient detail to permit adequate analysis.

The system of classification must be simple.

If the workers are expected to classify and code their own activities, the categories must be relatively few in number and so clearly defined that, after proper instruction and a trial run, the workers can classify their activities with ease and without appreciable error. Further analysis of any one category of activities can be made by the research staff, if detailed activity inventories of the workers are obtained simultaneously through interviews, and if the activity inventory classification is related to the time-study classification. Ultimately, such analyses were possible in the Yale project.

Initial Developmental Efforts

Answers to two questions were fundamental to the conduct of the time study. What infor-

List of Activity Categories

1. **Other Agencies.** (Not joint program planning, which is No. 9.) Organizing and participating in the planning of relationships with, and securing support for program from, other agencies and officials. Examples: hospitals, voluntary agencies, boards of education, mayor, legislature, civil service, finance department, welfare agencies, health departments at same level.

2. **Other Health Departments.** (Not at same level, which is No. 1.) Organizing and participating in the planning of relationships and consulting with health departments at different governmental levels. Examples: planning for financial support, exchange of services or personnel, joint programs.

3. **Giving Professional Education.** (Not inservice, which is No. 17 and No. 18.) Planning, organizing, participating in the giving of professional education. Examples: preparing, organizing and conducting workshops, formal classes in colleges and professional schools, lectures at professional societies.

4. **Group Organization.** Planning for, organizing, and training specific purpose groups. Examples: X-ray survey committees, fact-finding groups, study groups, volunteers in clinics.

5. **Talks to Public.** Planning, preparing, and delivering talks to public. Examples: mothers' classes, high schools, service clubs, PTA's, food handlers.

6. **Planning Mass Media.** (Not its preparation, which is No. 10.) Planning content and employment of mass media of communication. Examples:

audiovisual aids, pamphlets, newspaper publicity, radio scripts.

7. **Information Service.** (Not as part of case visit, which is No. 10.) Answering individual requests for information and escorting visitors through the health department.

8. **Health Department Program Planning.** Within the health department, planning research into health needs and planning the initiation, revision, scope, methods of execution, operating policy, and evaluation of health programs.

9. **Joint Program Planning.** Working with other agencies to plan research into health needs and to plan the initiation, revision, scope, methods of execution, operating policy, and the evaluation of health programs.

10. **"Technical."** (Not arithmetic computations, posting, adding and transcribing reports, distributing mass media, which are No. 11.) Primary medical, professional, technical activities such as:

Examination and treatment of patients, home visits, environmental sanitation visits, advice to clients and patients, taking medical and social histories, epidemiological investigations.

Laboratory and other test procedures, reading X-rays, preparation of mass media, planning and editing the annual report, preparing budgets and diets, statistical analysis.

11. **"Ancillary."** (Not giving information to clients, which is No. 7.) Essential supporting activities, such as:

mation was the time study to elicit? How was the desired information to be obtained?

The initial plan was to match with time allocations the detailed activity information obtained from interviews and observation. The information was to be obtained from time kept by participants in their own words.

Toward the end of 1950, the first formulation of time-study content and method was completed.

A time-log form was designed to describe what activities a public health worker does, how the worker performs them, and approximate time involved. It consisted of two columns: a narrow left-hand column in which time intervals were specified and a wider right-hand column.

The first column, one headed "What: Job Activity," and the other, "How: Means of Performance."

Below the columns were instructions for the use of the log.

suggested simply that each activity be recorded in terms of what, how, and how long. A partial list of activities and the way in which these activities might be performed was furnished as a guide. The list named about 60 possible activities, such as investigation, survey, clinic examination, sample collection, and school visit, and about 50 areas in which these activities could be performed, such as tuberculosis, civilian defense, epidemiology, and venereal disease. Coding and analysis of the completed time logs were to be performed by the research staff in accordance with the basic activity codes developed for the interview part of the project.

A pilot run of this time study, including careful orientation of the participants, was undertaken in one local health department. The inadequacies of this approach were soon apparent.

List of Activity Categories—Continued

or clinic and obtaining identifying information (name, address, etc.) from clients. All keeping, compilation of reports, filling out of forms (includes daily time-keeping).

Education, media making, issuing of orders and developing X-rays.

Distributing mass media, filing, geographing, opening and distributing mail, transferring and receiving, making appointments.

Management. (Not activities with clerical, which are No. 1 and 2.)

Orders, keeping accounts, planning, performing computations.

1.) Planning, preparing, the budget. Examples: with vendors, planning projects, authorizing purchase orders, allotting funds.

Management. Planning and "keeping" activities.

Filing report, record, construction and maintenance of services; building.

Supervising performance, selecting, and authorizing personnel. Examples: interviewing, setting standards,

reviewing credentials, recommending or giving disciplinary action, counseling re personal problems or vocational guidance, writing letters of recommendation.

15. Personnel Supervision. (Not training, which is No. 17.) Giving immediate personal direction to a staff member. Examples: giving assignments, review through observation, discussions, analysis of records or reports.

16. Receiving Supervision. Receiving the services described in No. 14 or the supervision described in No. 15.

17. Individual Inservice Training. Planning, organizing, and giving inservice training and education for individuals. Examples: conferences, close collaboration, field trips, provision of study outside the department.

18. Group Inservice Training. Planning, organizing, and giving inservice training and education for groups of workers. Examples: lectures, staff meetings, field trips.

19. Own Education and Training. Attending professional meetings, classes, workshops, staff meetings; reading professional literature; field orientation; receiving inservice training.

20. Social Activities. Achieving and maintaining rapport with co-workers, "passing the time of day," social conversations, arranging for office parties.

21. Personal. Meals, coffee hours, rest periods, sick leave, dentist and doctor appointments.

The other, the Flury strain of modified live virus rabies vaccine, produced in embryonated hen's eggs, protects for 4 years, and possibly for life. We have had extensive field experience since 1946 with both types of vaccine.

In upper New York State, where wildlife rabies is endemic in approximately one-third of the area, and where 314 to 1,175 laboratory confirmed cases have been reported annually since 1944, canine rabies has been dramatically controlled since the dog program was initiated early in 1946. Fifth, a publicity campaign designed to make the public aware of the importance of the above measures.

On Vaccination of Animals

KOPROWSKI: Now, I would like to have the members of the panel discuss briefly the vaccination of animals other than dogs, chiefly cats and cattle, since they, too, were involved in the epidemic in Simona.

TIERKEL: We didn't include cats in our mass vaccination programs. Private owners can vaccinate cats. We find that rabies in cats disappears when dog rabies is under control.

DEAN: This is undoubtedly true where only canine rabies exists. Our experience indicates that cat rabies is associated with the disease in foxes.

KOPROWSKI: What about the vaccination of cattle?

STARR: Loss of cattle as a result of rabies was so heavy in Georgia that the State legislature considered free vaccination of cattle.

We tried chick embryo vaccine on test herds. On the last round, we inoculated 19 herds in a rabies endemic area, leaving 25 percent unvaccinated for controls (1,107 animals inoculated in all), but since none of the animals

by rabies, the experiment was inconclusive except to show that on this round the avianized rabies vaccine did not harm the animals.

We then purchased cattle, inoculated them, and challenged with rabies. Five of the 16 vaccinated cows died, but 12 of the 16 unvaccinated cows died of rabies.

It should be noted that the 5 deaths occurred in animals which had been vaccinated as calves. All animals vaccinated as adults survived challenge. This indicates that the immunity induced is not as solid in young adults and that young animals should be revaccinated.

KOPROWSKI: While all these control measures were being discussed in Simona, rabies spread through wildlife species to an alarming degree. In two places bats were reported to have attacked children. However, before we go over to the bat problem, it is perhaps advisable to discuss a comprehensive program of ecologic studies aimed at elucidating the following points:

How many species are involved?

Is there a possibility of silent carriers?

Do all animals infected with street virus die?

TIERKEL: As Dr. Dean has mentioned, one of the first problems we must attempt to solve is a quantitative relationship between population density of wild animal vectors, such as foxes, and prevalence of the disease in those populations. We must find the population density threshold which will no longer support a rabies epizootic.

The bizarre geographic and cyclic pattern of sylvatic rabies outbreaks has suggested to some the possibility of a symptomless carrier state in foxes and skunks. Along this line, information must be obtained on whether there is natural immunity and recovery in these animals.

Still others feel that there may be unknown reservoirs of rabies in the wild, such as in various species of small mammals which may have been overlooked. This also suggests a possibility that there may be other routes of transmission in wild animals.

Other problems which should be studied are velocity of the geographic movement of infection and the relationship of bat rabies to the disease in terrestrial animals.

On Bat Rabies

KOPROWSKI: What about bat rabies?

The two bats which were caught in Simona after attacking children were forwarded to the nearest public health laboratory and subjected to diagnostic studies. Mice inoculated with their brain or salivary gland tissue developed rabies.

TIERKEL: Many bat species are turning up rabid. It started in 1953 when a Florida yellow bat attacked a child. Then in Pennsylvania a woman was attacked by a different species of bat. These episodes aroused the interest of public health workers in many areas and prompted surveys throughout the country.

Thus far, rabid bats have been found in Florida, Pennsylvania, Texas, California, and Montana. Over 40 isolations have been made from 6 different species of insectivorous bats of free-living and colonial or cave-dwelling varieties.

In Texas, Lt. Col. Kenneth F. Burns reports that 65 percent of 207 pooled bat serums showed rabies antibodies by serum neutralization test. There is much research work that needs to be done to determine the epidemiological significance of these findings.

KOPROWSKI: It's hard to recognize rabid bats since we don't know what to expect in the behavior of a normal bat. According to Colonel Burns, it's hard to distinguish the way bats act when rabid from the effect of DDT, which also affects the nervous system.

Are insectivorous bats as great a menace to the animal population as the hematophagous species?

Is there evidence for symptomatic carriage in bats?

TIERKEL: We do not have enough clinical experience with bats so we must rely on laboratory findings. It has been observed that when vampire bats in Latin America are rabid they often fly in the daytime instead

of at night. On the other hand, vampires are capable of transmitting rabies to people and animals without showing visible signs of illness. We have yet to discover whether this is true of the rabid insectivorous bats found in the United States.

DEAN: Anything we say about the bat problem is premature. We first thought that only free-living bats were infected but then found rabies in colonial bats as well.

There are two schools of thought. One group thinks that bat rabies in this country represents an extension of the disease from Mexico, Trinidad, or South America, the invasion of a new disease among bats in the United States. Rabies among vampire bats south of the border is an old problem. In this connection migratory bats have been tagged traveling as far as 800 miles. There is a banding program under way to check this. Another group feels that rabies in bats has existed in this country for many years. Knowledge concerning bats and bat rabies is grossly inadequate.

We note that there is an unusually long incubation period in bat rabies with the Florida experience indicating that clinical illness lasts longer before death than in other species. We don't know how bats get the disease except from other bats, but we do know that they pass it on to other species. Unprovoked attacks by rabid bats suggest that they have undergone mental changes.

SELLERS: The finding of infected bats in so many widely separated areas of this country seems to me to strongly indicate that rabies has been in our bats for a long time.

KOPROWSKI: To summarize our knowledge of bat rabies, then:

All bats are suspect, insectivorous as well as hematophagous.

Brain and salivary gland tissue of any bat which attacks a human being should be studied in a laboratory for the presence of rabies virus.
